

149. Max Points on a Line

Hard Geometry Array Hash Table Math

[Leetcode Link](#)

Problem Description

The problem presents a set of points on a 2D coordinate system and asks us to find the maximum number of points that align straightly. In simple terms, we are to determine the largest group of points that lie on the same line. This is a geometric problem commonly encountered in computer graphics and spatial analysis and has significant implications in understanding patterns and relationships between data points in a 2D space.

Intuition

The intuition behind the solution begins with the realization that to find points on the same line, we need to consider the slope formed by pairs of points. In mathematics, the slope of a line is a number that describes both the direction and the steepness of the line.

The key idea for this solution is to iterate through each point and calculate slopes it forms with all other points. If two different lines share the same slope and have a common point, it means they are the same line. However, calculating slopes as floating-point numbers can cause precision issues. To circumvent this, we represent slopes as fractional tuples (**dy**, **dx**) where **dy** is the change in y (rise) and **dx** is the change in x (run).

Before creating this tuple, we need to reduce these values to their simplest form so that the slopes are uniformly represented. This is where the greatest common divisor (GCD) comes in: if we divide both **dy** and **dx** by their GCD, we get the smallest identical tuple for all points on the same line.

As we calculate these slope tuples, we store and count them using a hash structure, a **Counter** in Python, which keeps the count of each distinct slope seen from a specific starting point. The maximum count of these slopes, plus 1 (for the starting point itself), will indicate the maximum number of points on the same line from that point. We track the overall maximum as we loop through each point to solve the problem.

Solution Approach

The solution uses a brute-force approach along with some mathematical optimizations to reduce computational complexity. Below is the step-by-step breakdown of the implementation:

- The **gcd** function is defined to find the greatest common divisor of two numbers. It's a classic algorithm known as Euclid's algorithm, which is a recursive approach to successively finding remainders until it lands a zero, thereby finding the GCD of the initial pair.
- We start by initializing the **ans** to 1 which represents the default maximum number of points on a line that can always include the point itself.
- We iterate over each point **points[i]** in the outer loop. This point will act as a reference or starting point to calculate slopes with every other point.
- For a given reference point, we create a **Counter** object to keep track of all the slopes we calculate from the reference point to all other points.
- The inner loop starts from **points[i + 1]** to the end of the array, ensuring we don't repeat calculations for pairs of points that we have already checked.
- For every point **points[j]** in this inner loop, we calculate the differences **dx** and **dy**. These represent the horizontal and vertical distances between the points.
- We then call our **gcd** function with **dx** and **dy** to get the greatest common divisor of the two differences, **g**.
- With **g**, we normalize **dx** and **dy** by dividing both by **g**. This step ensures we are working with the simplest form of the ratio that defines the slope. We store this normalized pair as a tuple **k**.
- The **Counter** object, **cnt**, updates or increments the count for the tuple **k**, effectively counting how many points have formed the exact same slope with the starting point.
- As we increment the count, we also keep track of the maximum value so far with **ans = max(ans, cnt[k] + 1)**. We add 1 because the count in **cnt** does not include the starting point.
- After considering all pairs starting from each point **points[i]**, the final value of **ans** will be the maximum number of points that lie on the same line.

This approach is exhaustive in that it compares all pairs, but it's efficient in ensuring the numerical stability and uniqueness of the slopes by using the GCD and normalizing the differences. Although the time complexity can be high for very large input arrays, this method is quite practical and straightforward when dealing with typical problem constraints seen in coding interviews.

Example Walkthrough

To illustrate the solution approach, let's consider a small example. Suppose we have the following set of points on a 2D coordinate system: [(1,1), (2,2), (3,3), (2,3), (3,2)].

- We begin by initializing **ans** to 1.
- Starting with the first point, **(1,1)**, we create a **Counter** object called **cnt** to store the slopes of lines formed with this point and others.
- We skip comparing **(1,1)** with itself and move on to calculate the slope with the second point **(2,2)**. The change is **dx = 2-1 = 1** and **dy = 2-1 = 1**. We find the GCD of **dx** and **dy**, which is 1, and normalize to get the slope tuple **(dy/dx) = (1/1)**.
- We update the counter by setting **cnt[(1,1)]** to 1, indicating that there's one line with this slope from the start point.
- Next, we calculate the slope between **(1,1)** and **(3,3)**. The change is **dx = 3-1 = 2** and **dy = 3-1 = 2**. The GCD is 2, and the normalized slope tuple is **(1,1)**. We increment **cnt[(1,1)]** to 2.
- Now, we check the slope between **(1,1)** and **(2,3)**. Here, **dx = 2-1 = 1**, **dy = 3-1 = 2**. The GCD is 1, so the tuple becomes **(2,1)**. We store this new slope in the counter with **cnt[(2,1)] = 1**.
- Finally for point **(1,1)**, we calculate the slope between **(1,1)** and **(3,2)**. The changes are **dx = 3-1 = 2** and **dy = 2-1 = 1**, with the GCD being 1, leading to a slope tuple **(1,2)**. We put **cnt[(1,2)] = 1**.
- We now compare the counter values to **ans**. For slope **(1,1)**, we have 2 count, which makes **ans = max(1, 2+1)** (we add 1 to include the reference point).
- Repeat the process from points **(2,2)**, **(3,3)**, **(2,3)**, and **(3,2)**. Each time we update **cnt** and **ans** appropriately.

Upon completing the loops, we find that the slope **(1,1)** has the highest count, thus the maximum number of points aligning straightly is **ans**, which now equates to 3, taken from the three collinear points **(1,1)**, **(2,2)**, and **(3,3)**.

This step-by-step iteration through each point and counting slope occurrences provides us with the required result. This approach will be applied to all points and all possible slopes to ensure we find the maximum number of collinear points.

Python Solution

```
1 from collections import Counter
2
3 class Solution:
4     def maxPoints(self, points):
5         """
6         Calculates the maximum number of points that lie on a straight line.
7
8         :param points: A list of point coordinates [x, y].
9         :type points: List[List[int]]
10        :return: The maximum number of points on a straight line.
11        :rtype: int
12        """
13
14        def calculate_gcd(a, b):
15            """

26
27                 // Create a unique key for the slope by concatenating deltaX and deltaY divided by their GCD
28                 std::string slopeKey = std::to_string(deltaX / gcdSlope) + "," + std::to_string(deltaY / gcdSlope);
29
30                 // Increment the count of points for the current slope
31                 slopeCount[slopeKey]++;
32                 // Update maxPointsOnLine if the current slope has more points than the maximum recorded so far
33                 maxPointsOnLine = std::max(maxPointsOnLine, slopeCount[slopeKey] + 1);
34             }
35         }
36         return maxPointsOnLine; // Return the maximum number of points on a line
37     };
38 };
39
```

Typescript Solution

```
1 // Import statements from TypeScript/JavaScript are not required here as we're defining global variables and methods.
2
3 // Helper function to find the Greatest Common Divisor (GCD) of two numbers
4 function gcd(a: number, b: number): number {
5     // If b is 0, a is the GCD
6     return b === 0 ? a : gcd(b, a % b);
7 }
8
9 // Function to find the maximum number of points that lie on a straight line
10 function maxPoints(points: number[][]): number {
11     const numOfPoints = points.length; // Number of points
12     let maxPointsOnLine = 1; // Initialize to 1 since a single point technically forms a line
13
14     // Iterate through each point to use as a starting point
15     for (let i = 0; i < numOfPoints; ++i) {
16         const x1 = points[i][0], y1 = points[i][1]; // Coordinates for the current point
17         let slopeCount: { [key: string]: number } = {}; // Map to keep track of slopes and their counts
18
19         // Iterate through remaining points to form lines and calculate slopes
20         for (let j = i + 1; j < numOfPoints; ++j) {
21             const x2 = points[j][0], y2 = points[j][1]; // Coordinates for the next point
22             let deltaX = x2 - x1, deltaY = y2 - y1; // Differences in x and y coordinates (components of the slope)
23             const commonDivisor = gcd(deltaX, deltaY); // Calculate GCD to standardize the slope representation
24
25             // Create a unique key for the slope by concatenating normalized deltaX and deltaY
26             const slopeKey = `${deltaX / commonDivisor},${deltaY / commonDivisor}`;
27
28             // Increment the count of points for the current normalized slope
29             slopeCount[slopeKey] = (slopeCount[slopeKey] || 0) + 1;
30             // Update maxPointsOnLine if the current slope has more points than the maximum recorded so far
31             maxPointsOnLine = Math.max(maxPointsOnLine, slopeCount[slopeKey] + 1);
32         }
33     }
34
35     return maxPointsOnLine; // Return the maximum number of points on a line
36 }
37
38 // Example usage:
39 // const result = maxPoints([(1,1),[2,2],[3,3]]);
40 // console.log(result); // Output would be 3
41
```

Time and Space Complexity

Time Complexity

The time complexity of the given code is determined by two nested loops iterating over the points and the calculation of the greatest common divisor (gcd) for each pair of points. The outer loop runs **n** times (where **n** is the number of points), and the inner loop runs progressively fewer times as **i** increases, leading to a sum of the series from 1 to **n-1**, which is $(n-1)n/2$. The gcd calculation has a time complexity that is generally $O(\log(\min(a, b)))$, where **a** and **b** are the differences in the x and y coordinates of two points.

Overall, the time complexity is $O(n^2 * \log(\min(dx, dy)))$, since the gcd computation is the most significant operation in the inner loop.

```
1 O(n^2 * log(min(dx, dy)))
```

Space Complexity

The space complexity of the code is largely influenced by the **Counter** dictionary storing each unique slope encountered. In the worst case, every pair of points could have a unique slope, leading to $O(n^2)$ entries in the **Counter**. However, this is very unlikely in a standard dataset, and thus the space complexity would typically be much lower.

The recursive nature of the **gcd** function also adds to the space complexity, due to the call stack. However, because the depth of the recursion is $O(\log(\min(a, b)))$, this does not significantly affect the overall space complexity.

Thus, the worst-case space complexity is:

```
1 O(n^2)
```

But on average, it would be significantly better, depending on how many points share the same slope.
