455. Assign Cookies

Two Pointers

Sorting

Problem Description

given certain constraints. Each child has a greed factor, g[i], which indicates the minimum size of a cookie that will make them content. Similarly, each cookie has a size, s[j]. A cookie can only make a child content if the size of the cookie is greater than or equal to the child's greed factor. The objective is to assign cookies to children in such a manner that the maximum number of children are content. A child can receive at most one cookie, and a cookie can only be assigned to one child. The task is to calculate the maximum number of content children based on the distribution of cookies according to the children's greed factors.

The problem describes a scenario where a parent wants to distribute cookies to their children in a way that maximizes happiness,

The intuition behind the solution is to prioritize giving cookies to children with the smallest greed factor first. We can sort both

Intuition

factors, trying to find the smallest cookie that meets or exceeds that greed factor. If such a cookie is found, we assign it to the child, making them content, and move on to the next child. Once a cookie has been assigned, it can no longer be given to any other child, so we move to the next available cookie.

the children's greed factors (g) and the cookie sizes (s) in non-decreasing order. We then iterate through the sorted greed

large cookie on a child who would be content with a smaller one. By efficiently matching cookies to children starting with the least greedy ones, we aim to maximize the total number of content children. As we iterate through the greed factors, if we reach a point where there are no more cookies left to satisfy a child, we return the

The reason for sorting is to use the smallest cookies for children with the lowest greed factor, which ensures we don't waste a

number of children that have been made content so far. If all children have been assigned a cookie, we return the total number of children.

Solution Approach

The solution approach uses a greedy algorithm which is an algorithmic paradigm that builds up a solution piece by piece, always

choosing the next piece that offers the most immediate benefit. In this case, the immediate benefit is making a child content with

The algorithm works as follows:

3.

the smallest cookie possible.

total number of content children.

Following the steps outlined in the solution approach:

greed factor to the current cookie size:

the boundary of array s).

Solution Implementation

greed_factors.sort()

cookie_index += 1

return child index

// Return the final count of content children

// Sort the greed factors of the children

std::sort(cookies.begin(), cookies.end());

// Sort the sizes of the cookies

int contentChildren = 0;

// Iterate through each child

++cookieIndex;

if (cookieIndex < numCookies) {</pre>

++contentChildren;

// Give the cookie to the child

std::sort(children.begin(), children.end());

int numChildren = children.size(); // Number of children

// If we found a cookie that can satisfy the child

int numCookies = cookies.size(); // Number of cookies

int findContentChildren(std::vector<int>& children, std::vector<int>& cookies) {

for (int childIndex = 0, cookieIndex = 0; childIndex < numChildren; ++childIndex) {</pre>

while (cookieIndex < numCookies && cookies[cookieIndex] < children[childIndex]) {</pre>

// Find the first cookie that can satisfy the current child's greed factor

// Counter for content children

return contentChildrenCount;

cookie_index += 1

return len(greed_factors)

cookie_sizes.sort()

Sort the greed factors array g and the cookie sizes array s in ascending order. This sorting is crucial as it allows us to efficiently assign the smallest available cookie that will make each child content.

For the current child's greed factor (g[i]), iterate through the cookies starting from the current index j in the array s until you

Loop through each child's greed factor in g, with the index i iterating through g.

- find a cookie large enough to satisfy this child. This inner while loop continues as long as j < len(s) and the current cookie is smaller than the current child's greed factor (s[j] < g[i]). If the current cookie is too small, increment j to check the next
- cookie.

greed factors g = [1, 2, 3] and an assortment of four cookies with sizes s = [1, 1, 3, 4].

Initialize a pointer j to 0, which will track the current index in the cookie sizes array s.

with the next child by proceeding to the next iteration of the for loop. If all children have been considered, return the length of g as all children have been made content.

If j is equal to or greater than the length of s, meaning there are no more cookies left to distribute, return the index i as the

If a suitable cookie is found (one that is equal to or larger than g[i]), increment j to move to the next cookie and continue

The performance of this algorithm hinges on the sorting process (which typically runs in O(n log n) time). The following loop operations are linear, making the total time complexity O(n log n) primarily due to sorting, where n is the number of elements in

the larger of the two arrays g or s. Space complexity is O(1) since the solution sorts and iterates over the input arrays in place

without using extra space for auxiliary data structures. **Example Walkthrough**

Let's consider the following example to illustrate the solution approach. Imagine a scenario where we have three children with

are now sorted in ascending order. Initialize a pointer j to 0 to track the current index in the sorted cookie sizes array s. Loop through each child's greed factor in g. We start with the first child g [0], which is 1.

First, sort the arrays g and s. Since g is already sorted, we only need to sort s, which becomes s = [1, 1, 3, 4]. Both arrays

For the current child's greed factor (g[i]), loop through the cookies starting from the current j index. We compare the child's

We now check for the second child (g[1] = 2). Since we have incremented j, the cookie we are looking at is now s[1] which

∘ For the first child (g[0] = 1), the first cookie (s[0] = 1) is of size 1, which satisfies the child's greed factor. We increment j to 1 and move to the next child.

• Now looking at cookie s [2] which is of size 3, it satisfies the second child's need (g [1] = 2). We increment j to 3 and move to the next child. For the third child (g[2] = 3), the next cookie is s[3] = 4, which is also sufficient. We increment j to 4 (which now is outside

allowed us to efficiently match the smallest possible cookie to each child according to their greed factor.

def findContentChildren(self, greed_factors: List[int], cookie_sizes: List[int]) -> int:

while cookie_index < len(cookie_sizes) and cookie_sizes[cookie_index] < greed:</pre>

Move to the next cookie index assuming the current cookie has been used

All children have been content, return the total number of children

Sort the greed factors of the children and the sizes of the cookies

is of size 1. However, 1 is smaller than the greed factor 2. So, we increment j to 2.

- Since all the children's greed factors have been considered and satisfied, we return the length of g, which is 3. This indicates that all children have been made content. By following the algorithm, we have maximized the number of content children with the available cookies. The sorted arrays

class Solution:

iterating through them to find content children.

Time Complexity

Sorting: Both the lists g and s are sorted at the beginning of the function. The sorting operation typically has a time complexity of O(n log n) for an average sorting algorithm like Timsort (used in Python's sort() method), where n is the

The time complexity of the provided code can be analyzed based on two main operations: sorting the lists g and s and then

- number of elements in the list. If g has N elements and s has M elements, the total time for sorting would be O(N log N + M log M). Iterating through Lists: After sorting, the code uses a while loop within a for loop to find matches for g[i]. In the worst-case scenario, every element of g would be compared with every element of s, which gives us a time complexity of O(N+M), as each list is traversed at most once.
- Combining both steps, the overall time complexity is $0(N \log N + M \log M)$ for the sorting part, which is dominant, plus 0(N+M)for the iteration part. Therefore, the total time complexity is:
- The space complexity is the amount of extra space or temporary space used by an algorithm. The provided code only uses a

 $O(N \log N + M \log M)$.

0(1).

Space Complexity

fixed number of variables (i, x, j) and does not create any auxiliary data structures proportional to the size of the input. The space taken up by the input lists themselves is not counted towards the space complexity, as they are part of the input. Therefore, the space complexity is:
