953. Verifying an Alien Dictionary String Hash Table Array Easy

Problem Description

different ordering of these letters. This order is represented by the string order, where each character's position indicates its rank in the alien alphabetical order. We're given a list of words called words, which are supposedly written in this alien language. Our task is to determine if these words are sorted according to the alien lexicographical order. To put it simply, we need to confirm if each word would appear before the

In the given problem, we're dealing with a hypothetical alien language that uses the same lowercase letters as English but has a

following word in a dictionary organized by the provided alien alphabet. The lexicographical order is similar to what we're familiar with in an English dictionary—'apple' comes before 'banana' because 'a' is

before 'b' in the English alphabetical order. However, for this problem, we need to ignore the English alphabetical order and instead use the provided order string to determine the sorting sequence.

a point and then greater according to the alien alphabet, or entirely greater if compared at the same position in each word.

In essence, we need to write a function that checks this sorting without reordering the list—a simple 'yes' or 'no' to whether the list is already sorted as per the alien dictionary.

To solve this, we have to read the words list using the alien alphabet and confirm that each subsequent word is either the same up to

Intuition The intuition behind the provided solution approach is to use a dictionary named m to represent the mapping of each character in the

alien language to its corresponding index according to order. Once we have this mapping, it is much easier to compare the words.

During the comparison, we want to ensure that for each position i up to the length of the longest word (in this case, arbitrarily

chosen as 20, assuming no word is longer than 20 characters), the following holds true: • If the character at position i in the previous word has a higher index in our alien dictionary than the character at position i in the current word, we should immediately return False, as this indicates that the list is not sorted.

 If characters at position i are the same, we continue our checks without concluding anything just yet because the subsequent characters might determine the order. • If at this position i, we do not encounter any characters that are out of order, and all comparisons were either equal or in sorted

- order, we can return True as this means the list is sorted correctly up to this character. • If after checking all positions i, we haven't returned False, it is safe to assume that the list is sorted according to the alien language, and we return True.
- Solution Approach
- The solution provided makes use of a hash table (or dictionary in Python) and single-pass comparisons to implement the algorithm. Here's a step-by-step breakdown of the implementation:

position in the order string. This mapping allows us to efficiently translate each character in the alien words into its

1. Mapping the Order: We start by creating a dictionary m where the key is each character of the alien alphabet and the value is its

1 prev = -1

2 if prev > curr:

1 if prev == curr:

we continue.

1 if valid:

valid = False

return True

5. Validating Sequential Characters:

characters to determine the order.

Using enumerate, each character c is paired with its index i, effectively creating a rank ordering for the alien alphabet.

2. Comparing Characters in Words: The code uses a for loop to iterate over the positions of the characters in the words, up to a

predefined limit of 20 (assuming that none of the words will be longer than that). For each position i, it compares characters

from different words at the same index.

(prev) would mean the list is not sorted.

1 curr = -1 if i >= len(x) else m[x[i]]

corresponding rank in the alien language.

1 m = {c: i for i, c in enumerate(order)}

1 for i in range(20): 3. Tracking and Comparing Ranks of Characters: Inside the loop, two variables prev and curr are used to track the rank of the current and previous characters, respectively. Initially, prev is set to -1 to ensure that the first comparison is valid.

4. Checking Sorted Order: As we iterate over each word x in words, we check if the current character's rank is less than the

to track whether all characters compared up to that point have been the same, in which case we need to check further.

6. Early Termination: If at any point, we successfully pass through all the words and their characters at a certain index without

returning False, and valid remains True, it means we found a lexicographical order and can return True immediately. Otherwise,

previous one. Since we are performing lexicographical comparison, any current character (curr) with a lower rank than previous

return False 5. Validating Sequential Characters: If the previous character is the same as the current one, valid is set to False. valid is used

conclude that the words list is sorted according to the alien dictionary.

1 return True Key algorithms and data structures used in this implementation include the hash table for constant-time look-up, and a comparison framework that examines each word character-by-character using its index. The process of early termination after successful

sequential checks leverages a common pattern in sorting algorithms to optimize performance by avoiding unnecessary work.

Let's consider a small example to illustrate the solution approach. Imagine we are given the following alien order and a list of words:

• Using the provided order, we create a mapping m that will let us compare the characters based on their alien language order.

7. Final Verdict: If we reach the end of our positional checks (the for loop) without finding any characters out of order, we

 \circ We initialize prev = -1 to indicate the start of comparisons. We will compare the ranks of characters at each position within the words.

We set up a loop that will go up to 20, which is more than enough for our example.

Starting with "hello", we get the rank of 'h' as 0 for position 0. There's no previous word, so we move on.

■ In the mapping m, 'I' has a rank of 1 and 'h' has a rank of 0. Since 1 is greater than 0, the order is maintained.

Continue the loop until either the words are found to be in disorder or all characters are successfully compared.

If all characters are equal up to the minimum length of the two words, we also proceed to the next word in the list.

∘ In our example, if we found 'g' in "hello" greater than 'e' in "leetcode" at any given position, we would terminate and return

• However, since 'h' is less than 'l' at the first position and there are no other characters in disorder, we do not terminate early

We will walk through checking if the words are sorted according to this alien language.

○ The mapping would result in: {'h': 0, 'l': 1, 'a': 2, ... 'z': 25}.

When comparing characters at the same position, if they are equal, we proceed with further positions as we need more

We compare 'l' (at position 0) of "leetcode" with 'h' of "hello".

dictionary. In practice, the comparison process stops at the first instance where prev > curr. As "hello" and "leetcode" are in correct order in this alien language (since 'h' < 'l'), the result of our checks would be True. The words are indeed sorted according to the alien

After checking all positions and finding no disorder, we return True, meaning the list is sorted according to the alien

def isAlienSorted(self, words: List[str], order: str) -> bool: # Create a mapping from each alien character to its order index for easy comparison. order_index = {char: index for index, char in enumerate(order)} # Iterate up to 20 characters, assuming no word is longer than 20 characters. 6 for i in range(20): previous_index = -1 # Start with a comparison index of -1 for the first character.

Go through all the words to compare the characters at the current index i.

Else, use the mapped order index of the current character.

current_index = -1 if i >= len(word) else order_index[word[i]]

If all words are sorted until now, no need to check further characters.

// Subtract 'a' to convert char into an index (0-25), then assign its order

int previousIndex = -1; // Initialize previous character index as -1

for (int i = 0; i < 20; ++i) { // Iterate at most up to 20 times, the maximum word length

boolean isDistinct = true; // Flag to check if all chars at position i were unique so far

If the current index is greater than the word length, use a default index of -1.

Update the previous_index to the current character's order index for the next iteration.

If no problems were found in the above loop, the words list is sorted according to the alien language.

is_sorted_until_now = True # Flag to keep track of whether the order is sorted up to the current character index.

If the previous character's index is greater than the current character's index, the list is not sorted.

If the previous character's index is the same as the current, we can't be sure if it is sorted and need to check th

// Method to check if the words are sorted as per the given alien dictionary order public boolean isAlienSorted(String[] words, String order) { // Mapping from character to its position in the alien language int[] charIndexMapping = new int[26]; for (int i = 0; i < order.length(); ++i) {</pre>

```

function isAlienSorted(words: string[], order: string): boolean { // Create a mapping of each character to its position in the new language order const charPositionMap = new Map<string, number>(); for (const char of order) { charPositionMap.set(char, charPositionMap.size); 6

Typescript Solution

```
Time Complexity
The time complexity of the given code consists of a few different components:

    Creating a mapping (dictionary) m from characters to their alien order indices has a complexity of 0(1) because the number of

   characters in the order string is constant (assuming a fixed alphabet size, e.g., 26 for the English alphabet).
```

The outer loop runs a fixed 20 times which is a constant factor and thus does not impact the scalability of the algorithm. The

value 20 probably assumes that no word will be longer than 20 characters, which seems to be an arbitrary limit. However, this

• Inside the outer loop, there is an inner loop that iterates over each word in the words list. If the number of words is N, this gives

loop should ideally be in terms of the length of the longest word in words. It would be more accurate to consider it as O(L) where

- Within the inner loop, the operations are constant time, involving index lookup and comparison. Putting it all together, even with the arbitrary limit of 20 iterations, the actual scalable factor is the length of the words and the number of words. So the time complexity is O(L * N).
- **Space Complexity** • The space complexity for creating the m dictionary is 0(1), again because the alphabet size is constant.

• The code does not use any additional significant memory that scales with the input size, as all other variables are of fixed size

Thus, the overall space complexity of the code is 0(1).
