695. Max Area of Island

Problem Description

In the given LeetCode problem, we are provided with a 2D grid of 0s and 1s, where each 1 represents a piece of land, and 0s represent water. The grid represents a map where islands are formed by connecting adjacent 1s horizontally or vertically. We need to determine the size of the largest island in the grid, with the island's size being the count of 1s that make up the island. If no islands are present in the grid, the result should be 0.

Array

Leetcode Link

An example grid might look like this:

be 4 in this case.

In this grid, there are three islands with sizes 4, 1, and 2, respectively. The goal is to return the size of the largest island, which would

To solve this problem, we can use Depth-First Search (DFS) to explore each piece of land (1) and count its area. We iterate through

Intuition

setting it to 0 to ensure that each land cell is counted only once. This also helps to avoid infinite loops. The DFS algorithm explores the land in all four directions: up, down, left, and right. For each new land cell we find, we add 1 to the area of the current island and recursively continue the search from that new cell. Once we can't explore further (we hit 0s, or we

each cell of the grid; when we encounter a 1, we start a DFS traversal from that cell. As we visit each 1, we mark it as visited by

reach the grid's boundaries), the recursive calls will return the total area of that particular island to the initial call. By performing DFS on each 1 we find, we can calculate the area of each island. We keep track of the maximum area encountered during these searches. Once we've processed the whole grid, we have the largest island's area captured, and we return this as our

result. Solution Approach

The solution uses Depth-First Search (DFS), a classical algorithm for exploring all elements in a connected component of a grid,

graph, or network. In this scenario, "connected components" are the individual islands within the grid.

arguments.

The implementation consists of: 1. A helper function, dfs, which is a recursive function that takes the row and column indices (1, j) of a point in the grid as

2. Within dfs, we first check if the current cell contains a 1. If it contains a 0, it's either water or already visited, so we return an area

- of 0 for that cell. 3. If the current cell is a 1, we initiate the area of this part of the island with 1, and then set the cell to 0 to mark it as visited.
- 4. We define the possible directions we can explore from the current cell using the array dirs which contains the relative movements to visit top, right, bottom, and left adjacent cells. 5. We loop through each direction and calculate the new coordinates (x, y) for the adjacent cells. For each adjacent cell that is
- within the boundaries of the grid, we recursively call dfs. 6. The recursive dfs calls will return the area of the connected 1s, which we add to the area of the current island.
- At the top level of the maxAreaOfIsland function:
- 2. Then, we initiate a comprehensive search across all cells in the grid using list comprehension together with max function. Here, we only start a dfs traversal when we find a 1 (land cell).

7. After exploring all directions, the total area of the island, including the current cell, is returned.

3. Whichever cell starts a new DFS, the area of the connected island will be calculated completely before moving on to the next cell in the comprehension.

4. Finally, the maximum area found during the DFS traversals is returned.

1. We get the number of rows m and columns n of the grid.

- By marking visited cells and only initiating DFS on unvisited land cells, we ensure that each island's area is calculated once, which
- gives us the efficiency and correctness of the algorithm. This pattern of search and marking is common in problems dealing with connected components in a grid and is a handy technique to
- remember for similar problems.

in this case, as both islands are of size 1, the result should be 1.

Let's illustrate the solution approach with a small example. Consider the following 2D grid: 1 0 1

2 1 0 In this grid, there are two islands, each consisting of a single piece of land (1). We aim to find the size of the largest island, although

1. Begin by initializing maxArea to 0. This variable will keep track of the largest island area found.

the land (if they contain 1).

there are no new DFS calls.

flow of search using DFS in this context.

if grid[row][col] == 0:

directions = (-1, 0, 1, 0, -1)

return 0

Example Walkthrough

3. Let's start with the cell at (0,1). Since it's a land cell (1), we call the dfs function. 4. Inside dfs, we set the current cell to 0 to mark it visited and initialize the area to 1, since we already found one piece of land.

6. The dfs function is called on cell (1,0). Again, it will set the cell to 0, increment the area to 2, and check surrounding cells. 7. Since the adjacent cells are either water (0) or out of bounds, there are no further recursive calls, and the total area for this

Current cell is land, so mark it as visited by setting it to 0,

and start area count at 1 (for the current cell)

island is 1. 8. We return to the top level of the maxAreaOfIsland function and continue checking the next cells. Since all 1s have been visited,

5. The dfs function will check all adjacent cells (in our case, there is only one at (1,0)) and perform dfs on them if they are part of

2. The algorithm starts scanning the grid from the top-left cell. When it encounters a 1, it performs a DFS from that cell.

- 9. The maxArea of 1 found is the size of the largest island, which is returned. In this example, the algorithm correctly identifies the size of the largest island in the grid, which is 1, and demonstrates the typical
- Python Solution

         // Return the maximum area of an island found in the grid
 40
         return maxArea;
 41 }
 42
```

Time and Space Complexity

Time Complexity The time complexity of the algorithm is O(M * N), where M is the number of rows and N is the number of columns in the grid. This is because in the worst case, the entire grid could be filled with land (1's), and we would need to explore every cell exactly once. The

function dfs is called for each cell, but each cell is flipped to 0 once visited to avoid revisiting, ensuring each cell is processed only once.

Space Complexity

The space complexity is $0 \, (M * N)$ in the worst case, due to the call stack size in the case of a deep recursion caused by a large contiguous island. This would happen if the grid is filled with land (1's) and we start the depth-first search from one corner of the grid, the recursion would reach the maximum depth equal to the number of cells in the grid before it begins to unwind.
