# **Problem Description**

The problem provides a scenario that simulates the formation of water molecules (H20) using threads. These threads represent the elements hydrogen (H) and oxygen (0). The objective is to ensure that two hydrogen threads (H) and one oxygen thread (0) can proceed to form a water molecule by passing a barrier, but they must do so in groups of three (two H and one 0). The problem statement specifies the following constraints:

An oxygen thread has to wait at the barrier until two hydrogen threads are available so they can all proceed together.

- Similarly, a hydrogen thread must wait for another hydrogen thread and an oxygen thread before proceeding.
- The threads themselves do not need to be aware of their specific pairings; the key is to allow them to pass the barrier in

complete sets that form water molecules. The code needs to enforce these synchronization constraints to ensure that no thread is allowed through the barrier until its corresponding set is complete.

# The solution uses the concept of semaphores which are synchronization tools to control access to a common resource by

multiple threads in a concurrent system. In the context of this problem, semaphores are used to manage the passage of hydrogen and oxygen threads through the barrier. Here is the intuition behind the solution:

Semaphore for Hydrogen (self.h): This semaphore starts with a count of 2, allowing two hydrogen threads to acquire it and,

- once acquired, proceed to release a hydrogen molecule by calling releaseHydrogen(). The semaphore's count decrements with each acquire. When it reaches 0, it means two hydrogen threads have passed, and an oxygen thread can now be allowed to pass by calling self.o.release(). Semaphore for Oxygen (self.o): This semaphore starts with a count of 0, ensuring that no oxygen thread can proceed until it's allowed by hydrogen threads. When the semaphore for hydrogen reaches a count of 0 (meaning two hydrogens have been
- acquired), then self.o.release() is called to increase the count to 1, allowing one oxygen thread to acquire it and proceed to release an oxygen molecule by calling release0xygen(). After this, it resets the count of the hydrogen semaphore to 2 by calling self.h.release(2), allowing the next group of hydrogen threads to acquire and start the process again. **Solution Approach**

The implementation of the solution revolves around the use of semaphores, which are counted locks that indicate the status of a

## resource. In the context of the problem, they are used to control the number of hydrogen and oxygen threads that can pass the barrier to form a water molecule.

Here's the breakdown of the solution approach step by step: **Initialization of Semaphores:** 

o self.h: A semaphore representing the hydrogen atoms. It is initialized with a count of 2, indicating that at the start, two hydrogen threads

• self.o: A semaphore representing the oxygen atom. It is initialized with a count of 0 since we need two hydrogen atoms to be ready before

have passed and called self.o.release().

constraints required for the formation of water molecules:

an oxygen atom can proceed.

can proceed.

- **Hydrogen Method:** • self.h.acquire(): Each hydrogen thread calls this method to decrement the semaphore's count. If two hydrogen threads call it, the count will become 0 and no more hydrogen threads can proceed until it's reset.
- releaseHydrogen(): A callback function provided to the hydrogen method which, when invoked, signifies the passing of a hydrogen thread. After releasing hydrogen, the code checks if the value of the semaphore self.h is 0, which means two hydrogen threads have acquired the lock and passed. It then calls self.o.release() to increment the oxygen semaphore, signaling that an oxygen thread can proceed.

• self.o.acquire(): The oxygen thread calls this to wait until its count is greater than 0. This can only happen after two hydrogen threads

Oxygen Method:

matching between threads.

 self.h.release(2): After an oxygen thread has passed, the hydrogen semaphore is reset back to a count of 2 by releasing it twice. This allows the next pair of hydrogen threads to proceed and restart the cycle.

By coordinating the actions via semaphores, the solution can ensure that at any point in time, if three threads pass through the

o release0xygen(): A callback function provided to the oxygen method which, when invoked, signifies the passing of an oxygen thread.

barrier, they will always be in the H-H-0 combination, hence forming a water molecule. It establishes a pattern where exactly two hydrogen threads must pass before an oxygen thread can, and this cycle repeats for each water molecule produced. The algorithm guarantees that these conditions are met, allowing the correct formation of water molecules without any explicit

programming, and this solution uses them effectively to solve the given problem. **Example Walkthrough** Let's step through a small example to illustrate the solution approach using semaphores to enforce the synchronization

The use of semaphores is a classic synchronization mechanism for enforcing limits on access to resources in concurrent

Assume we have a sequence of threads representing hydrogen and oxygen atoms ready to form water molecules, like so: HHOHHO. • Step 1: Initialize semaphores self.h (count = 2) and self.o (count = 0).

### • Step 2: The first hydrogen thread H1 arrives and calls self.h.acquire(), decrementing the semaphore self.h count to 1. • Step 3: The second hydrogen thread H2 arrives and also calls self.h.acquire(), decrementing self.h's count to 0. Now, with 2 hydrogens

threads to proceed.

oxygen thread 02 to proceed.

concurrent programming.

Solution Implementation

proper ratio for water molecule formation.

ready, the code allows for an oxygen thread to proceed by calling self.o.release(), setting the semaphore self.o count to 1. • Step 4: The oxygen thread 01 arrives and calls self.o.acquire(), decrementing self.o's count back to 0. Now, H1 and H2 release their hydrogen atoms by invoking releaseHydrogen(), and 01 releases its oxygen atom by invoking release0xygen().

• Step 6: Now the self.h count is back at 2, another pair of hydrogen threads H3 and H4 arrive and each calls self.h.acquire(), reducing the semaphore self.h count back to 0.

• Step 7: Similar to step 3, since self.h's count is 0, self.o. release() is called again, incrementing self.o's count to 1 and allowing the next

• Step 5: After 01 releases the oxygen atom, self.h.release(2) is called, which resets self.h's count back to 2, allowing the next two hydrogen

- Step 8: 02 then calls self.o.acquire(), decreasing its count to 0, and this enables H3, H4, and 02 to release their atoms by invoking releaseHydrogen() and release0xygen(), respectively. • Step 9: The cycle repeats with self.h.release(2) resetting the hydrogen semaphore count after each oxygen atom is released, ensuring the
- Throughout this example, the semaphore mechanisms enforce the correct arrival order and combination for the threads, closely emulating the constraints of water molecule formation and demonstrating the effectiveness of semaphores for synchronization in

Time and Space Complexity

self.sem oxygen = Semaphore(0)

self.sem\_hydrogen.acquire()

# Semaphore for hydrogen starts at 2 since we need two hydrogen atoms.

# Semaphore for oxygen starts at 0 - it is released when we have two hydrogen atoms.

**Time Complexity** 

The time complexity of both hydrogen and oxygen methods in the H20 class can be described as O(1). These methods involve a

# fixed number of operations: a semaphore acquire operation and a semaphore release operation. The semaphore operations themselves have a constant time complexity since they are essentially atomic operations that manage an internal counter.

**Space Complexity** The space complexity of the H20 class is O(1). This is because the class maintains a constant number of semaphores with fixed space usage regardless of the number of invocations of the hydrogen and oxygen methods. No additional space that scales with the input size or the number of method calls is utilized.
