2171. Removing Minimum Number of Magic Beans

Problem Description

bag. Our task is to make the number of beans in each non-empty bag equal by removing beans from the bags. There are two conditions we need to obey: 1. We cannot add beans back to any bag once removed.

The LeetCode problem provides us with an array beans, in which each element represents the number of magic beans in a respective

Leetcode Link

- 2. After the removal, no bag should be empty; each should contain at least one bean.
- The goal is to determine the minimum number of beans that we need to eliminate to achieve equal amounts in all non-empty bags.

Intuition

To solve the problem, one might initially consider trying to make all bags have the same number of beans as the bag with the least

taking into account the total bean count. Given that we want all the non-empty bags to have an equal number of beans, a sensible approach is to make them all equal to a certain number and we never want that number to be more than the smallest non-zero number of beans in any bag. Therefore, we

amount, but that is not necessarily optimal. To minimize bean removal, we must intelligently decide which beans to remove while

can sort beans array first, which helps us consider potential equal bean counts in order. While iterating through the sorted array, we will simulate making all non-empty bags have the same number of beans as the current bag. The number of beans to remove will then be the total sum of beans minus the beans in the current bag times the number of

the remaining bags count (including the current bag). We repeat this process for each bag and keep track of the smallest number of beans we need to remove. This will give us the answer.

remaining bags. This is because each remaining bag will have the same number of beans as the current bag, so we multiply that by

Solution Approach The implementation uses a simple algorithm and takes advantage of the sorted properties of the array to reduce the number of

Here's the step-by-step approach, paired with the code provided:

beans removed to a minimum.

1. Sort the beans array. 1 beans.sort()

to the smallest possible non-zero count.

1 ans = s = sum(beans)3. Calculate the length of beans array and store it in variable n.

Sorting the array allows us to approach the problem in ascending order of bean counts, ensuring we always consider equalizing

2. Initialize the variable ans to the sum of beans; this represents the total count that will be considered for potential removal.

4. Iterate through each bag via its index i and the value v representing the number of beans in the current bag.

1 n = len(beans)

The mathematical formula here is crucial. s - v * (n - i) calculates the total number of beans to be removed if we decide that each remaining bag (including the current one) should contain v beans.

5. Calculate the number of beans to be removed if we make all non-empty bags equal to the current bag's bean count.

```
    v is the targeted number of beans for each bag.
```

1 return ans

1 for i, v in enumerate(beans):

1 ans = min(ans, s - v * (n - i))

We subtract from the total (s) the product of the targeted number of beans (v) and the remaining bags (n - i), which would give us the count of beans left if we were to equalize all bags to the current count v.

6. Return the smallest value of ans found through the iteration, which represents the minimum removal.

s is the total initial number of beans.

o n − i count of bags including and after the current one to be equalized.

and efficiency of this solution come from not needing a more complex data structure or pattern, as the problem can be solved with a single pass through a sorted array. Example Walkthrough

Let's illustrate the solution approach using a small example. Given the array beans = [4, 1, 6, 5], we want to make the number of

magic beans in each non-empty bag equal by removing the least number of beans possible, with the rule that no bags can be empty

This algorithm is efficient because it leverages the sorting of the array, which provides a natural order to consider potential equal

bean counts. The only significant data structure used is the list itself for storing and iterating over the bean counts. The simplicity

after the removal.

bag.

iteration):

3. We calculate the length of beans array, n = 4. 4. Now, we start iterating through the sorted beans array. On each iteration, we have the index i and the beans number v for each

5. As we iterate, we calculate the beans to be removed if we make all non-empty bags have v beans (the current bean count in our

2. We initialize ans to the sum of beans, which is in this case 1 + 4 + 5 + 6 = 16. At the same time, we store this sum in the variable

• With i=0, v=1: We could remove no beans, as every bag including and after can be 1. But since there is the maximum number

def minimumRemoval(self, beans: List[int]) -> int:

the initial answer before any removals

Iterate through the sorted bean piles

for i, num_beans in enumerate(beans):

Sort the list of beans to enable uniform removal

Calculate the sum of all the beans, this also represents

Initialize the minimum removals with the total sum as the upper bound

Calculate the current total after removing beans from the current pile onwards.

of bags here, this isn't optimal.

1. First, we sort the beans array to have beans = [1, 4, 5, 6].

 \circ With i=2, v=5: ans = min(4, 16 - 5 * (4-2)) which simplifies to ans = min(4, 16 - 10) resulting in ans = 4. \circ With i=3, v=6: ans = min(4, 16 - 6 * (4-3)) which is ans = min(4, 16 - 6) resulting in ans = 4. 6. After iterating through each bag, the smallest number of beans to remove is 4. Hence, the answer to the problem is 4, which is

 \circ With i=1, v=4: ans = min(16, 16 - 4 * (4-1)) which simplifies to ans = min(16, 16 - 12) resulting in ans = 4.

achieved by making all non-empty bags have 4 magic beans each (equalizing to the bag with 4 beans in it).

order to make the bags equal without leaving any empty, doing so efficiently by piggybacking off of the sorted nature of beans. Python Solution

By following this algorithm, we ensure we are checking every possible scenario to find the minimum beans we need to remove in

This means all piles to the right side of the current one (inclusive) 15 # will have 'num_beans' beans. 16 # The total beans removed will be the original sum minus the beans left. 17 18 current_total = total_sum - num_beans * (num_piles - i) 19 # Update the minimum removals if the current total is lower.

20 min_removals = min(min_removals, current_total) # Return the minimum number of beans that needs to be removed 21 22 return min_removals 23

Java Solution

beans.sort((a, b) => a - b);

let minBeansToRemove = totalBeans;

for (let index = 0; index < numOfBeans; index++) {</pre>

const numOfBeans = beans.length;

The given Python code snippet is designed to find the minimum number of beans that need to be removed so that all the remaining piles have the same number of beans. It first sorts the beans list, calculates the sum of all beans, and then iterates through the sorted list to find the minimum number of beans to remove.

Time Complexity

Time and Space Complexity

The time complexity of the code is determined by the sorting step and the iteration step.

2. The for loop iterates over the sorted list exactly once, which takes O(n) time.

// Sort the array of beans in ascending order for easier processing.

// Initialize the answer with the total number, as a worst-case scenario.

// Iterate through the beans array to find the minimum beans to remove.

minBeansToRemove = Math.min(currentRemoval, minBeansToRemove);

let currentRemoval = totalBeans - beans[index] * (numOfBeans - index);

// Calculate the total beans to remove if we make all the bags equal to beans[index].

// Update minBeansToRemove to the minimum of the current removal and previous minimum.

- 1. Sorting the beans list takes O(nlogn) time, where n is the number of elements in the beans list. This is because the .sort() method in Python uses TimSort, which has this time complexity.
- **Space Complexity**

Combining these two steps, the overall time complexity is O(nlogn) as this is the dominating term.

As for space complexity:

1. The sorting operation is done in-place, and does not require additional space proportional to the input size, so its space

- complexity is 0(1).
- 2. The variables ans, s, and n, and the iteration using i and v require constant space, which is also 0(1).

Therefore, the overall space complexity of the function is 0(1), indicating that it uses a constant amount of extra space.
