790. Domino and Tromino Tiling

```
Medium
        Dynamic Programming
```

Problem Description

You are given a problem related to tiling a 2 x n board with two types of shapes: a 2 x 1 domino and an L shaped tromino. The shapes can be rotated as needed to fit into the tiling of the board. The task is to find out how many different ways you can completely cover the 2 x n board using these tiles. It's important to note that two tilings are considered different only if there's at least one pair of adjacent cells in the board that is covered in one tiling and not covered in the other. Since the number of ways can be very large, the answer should be returned modulo 10^9 + 7.

```
Intuition
  To solve this problem, we can use <u>dynamic programming</u> because the problem has an optimal substructure and overlapping
  subproblems. Each state in our dynamic programming represents the number of ways to tile a board up to positions (i, j),
```

where \mathbf{i} is the position on the upper row and \mathbf{j} is the position on the lower row. Starting from a fully untiled board (0, 0), we consider all possible moves we can make with either of our two types of tiles—one

that takes us to (i + 1, j + 1) which represents placing a domino tile vertically, to (i + 2, j + 2) representing placing two domino tiles horizontally next to each other, to (i + 1, j + 2) or (i + 2, j + 1) representing placing a tromino tile. Every move is a transition to a new state, and the number of ways to tile the board for that state is the sum of ways of reaching it from all previous states.

The recursion ends when we consider the entire board tiled (i == n and j == n), which is our base case and we return 1 as there is exactly one way to have a whole tiled board from an entirely tiled board—do nothing. Since there are overlapping subproblems (we could reach a state from different previous moves), memoization via the @cache decorator is used to avoid redundant calculations. Lastly, every addition of ways is done modulo 10^9 + 7 to prevent integer

overflow and adhere to the problem constraints of returning the count of ways modulo 10^9 + 7. The solution to this problem makes use of a recursive depth-first search (DFS) approach along with memoization to count the

number of ways to tile the $2 \times n$ board. The DFS function dfs(i, j) is calculating the number of tilings for the board up to the point (i, j), bearing in mind that i and j represent the ending positions on the upper and lower rows, respectively.

The solution uses the @cache decorator to memorize intermediate results. This is because the DFS function will be called many times with the same arguments, and we want to avoid recalculating those results each time. The memoization optimizes our approach from an exponential time complexity to a polynomial time complexity.

Here is the step-by-step approach: 1. If either i or j exceeds n, we've gone beyond the board, which means this is not a valid tiling, so return 0. 2. If i = n and j = n, we succeeded in tiling the entire board and thus return 1. 3. If i == j, both rows are equally tiled thus far. We can place either two dominoes side by side (horizontally), one domino vertically, or a tromino (which will cover 2 x 1 area and one additional square either above or below). We accordingly call the dfs function for the following possible

next steps: dfs(i + 2, j + 2), dfs(i + 1, j + 1), dfs(i + 2, j + 1), and dfs(i + 1, j + 2).

```
4. If i > j, the upper row is ahead, so we can only place a domino horizontally on the lower row or a tromino that covers two cells on the lower row
  and one on the upper. Thus, the new states to go to are dfs(i, j + 2) and dfs(i + 1, j + 2).
```

- 5. If i < j, the lower row is ahead, so we can place a domino vertically on the upper row to reach dfs(i + 2, j) or place a tromino in a way that covers two cells on the upper row and one on the lower to reach dfs(i + 2, j + 1).
- returned modulo 10^9 + 7 as required by the problem statement. This result is then used for further calculations as we backtrack through the recursion. When the initial call to dfs(0, 0) completes, we have computed the total number of valid tilings for the entire board, and this

In each of these cases, we add up the counts returned by all possible step(s) taken from the current state, and this sum is then

result is returned as the final answer. **Example Walkthrough**

2. Since i == j, there are three moves we can consider: Place two horizontal dominoes to cover the whole first column, dfs(2, 2).

• Place one tromino (L-shaped), which will leave one cell in the second column on one of the rows uncovered, so we call both dfs(1, 2) and

Let's walk through a small example using a 2×3 board to illustrate the solution approach with the method dfs(i, j).

dfs(2, 1).

```
For each recursive call dfs(2, 2), dfs(1, 1), dfs(1, 2), and dfs(2, 1), repeat steps similar to step 2.
```

When calling dfs(2, 2) from dfs(0, 0): \circ i == j and they are equal to n, so it's a complete tiling and returns 1.

Start by calling dfs(0, 0) since no tiles have been placed yet.

Place one vertical domino to cover the first cells of both rows, dfs(1, 1).

When calling dfs(1, 1) from dfs(0, 0): • i == j, do the similar three steps:

When calling dfs(1, 2) from dfs(0, 0):

When calling dfs(2, 1) from dfs(0, 0):

• dfs(2, 3): Goes beyond the board, thus returns 0.

dfs(3, 3): Goes beyond the board, thus returns 0.

To get the result for dfs(0, 0) add up all the ways from the recursive calls:

From dfs(1, 1) we consider the result from dfs(2, 2), which is 1 way.

i < j, only two moves are possible:

• i > j, only two moves are possible:

- dfs(3, 3): Goes beyond the board, thus returns 0. dfs(2, 2): Complete tiling, returns 1. • dfs(2, 3) and dfs(3, 2): Goes beyond the board, thus both return 0.
- dfs(3, 2): Goes beyond the board, thus returns 0. • dfs(3, 3): Goes beyond the board, thus returns 0.

```
    Calls dfs(1, 2) and dfs(2, 1) do not add more ways as they result in 0 valid tilings.

So, dfs(0, 0) would return 1 (from dfs(2, 2)) + 1 (from dfs(1, 1), which includes the result from dfs(2, 2)) modulo 10^9 +
7, giving us a total of 2 ways to tile the 2 \times 3 board.
```

the given domino and tromino shapes.

Solution Implementation

class Solution:

From dfs(2, 2) we got 1 way.

Python

Base case: If we exceed the board size, there's no way to tile.

When both rows have the same number of points covered by tiles.

If the first row has more tiles than the second row.

from functools import lru_cache # Import lru_cache for memoization

if first row > n or second row > n:

elif first_row > second_row:

Initialization of possible ways to tile.

def numTilings(self, n: int) -> int: # A helper function with memoization to count the number of ways to tile the board. # i represents the tiles placed in the first row, and j represents the tiles in the second row. @lru_cache(None) # Use lru_cache for memoization to improve performance def count_ways(first_row: int, second_row: int) -> int:

The result from dfs(0, 0) is the final answer for the problem, which is 2 different ways to completely cover the 2 x 3 board using

return 0 # Base case: If both rows are completely tiled, we've found one valid tiling. if first_row == n and second_row == n: return 1

count_ways(first_row + 2, second_row + 1) + # Place a 'L' shaped tromino.

count_ways(first_row + 1, second_row + 2) # Place an inverted 'L' shaped tromino.

ways = count_ways(first_row, second_row + 2) + count_ways(first_row + 1, second_row + 2)

           # Return the ways modulo MOD, which represents the maximum number of unique tilings.
           return ways % MOD
       # Define the modulo constant to prevent large number arithmetic issues.
       MOD = 10**9 + 7
       # Call the helper function with the initial states of the board (0 tiles placed).
       return count_ways(0, 0)
Time and Space Complexity
  The provided Python function numTilings is intended for finding the number of ways to tile a 2xN board with 2×1 dominos and
  trominoes (L-shaped tiles). This is a dynamic programming problem often posed on platforms like LeetCode.
```

potentially up to 4 recursive calls can be made, and since this algorithm calls the dfs with arguments up to n (both i and j), the time complexity is loosely bounded by a function of the form $O(4^m)$, where m represents the number of recursive steps needed to reach the base case from the current step.

The time complexity of the function is difficult to frame precisely due to the complex recursive structure. On every call to dfs,

However, due to memoization (caching of results), repeated states are not recalculated, significantly reducing the number of recursive calls. Memoization effectively ensures that each state of (i, j) where 0 <= i, j <= n is computed only once. Since i and j can take on n+1 possible values each, the actual time complexity can be approximated as $0(n^2)$.

Time Complexity

class Solution:

Space Complexity The space complexity consists of the space used by the memoization cache and the stack space used by the recursion. The cache will have an entry for each unique (i, j) pair, so it will consume 0(n^2) space. The stack space, in the worst case, could

n is reached. Therefore, the overall space complexity of the numTilings function can be considered as 0(n^2) due to the memoization cache, which is the dominating factor here.

be as deep as the maximum depth of recursive calls, which is O(n) because in the worst case we increase one of i or j by 1 until

So, the final analysis is:

• Time Complexity: 0(n^2), considering memoization Space Complexity: 0(n^2), due to the caching and the call stack
