# 309. Best Time to Buy and Sell Stock with Cooldown

Medium Array **Dynamic Programming** 

## **Problem Description**

calculate the maximum profit that can be achieved through making as many buy-and-sell transactions as you wish, with a specific restriction: after selling a stock, you must wait one day before buying again. To be more explicit, you can buy one share and then sell it. However, after you sell, you need to skip a day before you can initiate

In this challenge, you are given an array prices where prices[i] represents the price of a given stock on the i-th day. Your task is to

another purchase. This is called a cooldown period. Additionally, it is important to note that you cannot hold more than one share at a time; before you can buy another share, you must have already sold the previous one. Your goal is to find out the best strategy to maximize your profit under these terms.

### The intuition behind the solution involves dynamic programming. Since we cannot engage in a new transaction on the day following a

Intuition

considering the cooldown. We can maintain two states for each day that represent the decisions and conditions:

sale, we can make a decision for each day - to buy, sell, or rest (do nothing). The key is to track the profits of these decisions while

2. f1: The maximum profit we can have if we buy on the current day.

For day 0, our states would be initialized as for = 0 (we start with no stock and no cooldown) and f1 = -prices[0] (since buying the stock would cost us the price of the stock).

1. fo: The maximum profit we can have if we rest (do not buy or sell) on the current day or if we sell on the current day.

we cannot buy the stock on the same day we sell.

We need a third temporary variable f to store the previous value of fo (from the day before), which will be used to update f1 since

The <u>dynamic programming</u> transitions can be described as follows: • fo will be the maximum of itself (choose to rest, and profit doesn't change) or f1 + x (choosing to sell the stock bought at a cost

cooldown, which means subtracting the current price x from the profit made before cooldown indicated by f).

of f1, which means adding the current price x).

In each iteration, we go through the prices starting with the second day, because the first day's decisions are predetermined as for =

o and f1 = -prices[0]. The result returned will be f0, which indicates the maximum profit that could be made with the last action

• f1 will be the maximum of itself (choosing to do nothing with the previously bought stock) or f - x (buying a new stock after

being a rest or a sale. The implementation of this solution successfully combines the conditions of the problem into a dynamic iterative process that captures the essence of buy-and-sell strategies while complying with the cooldown constraint.

**Solution Approach** 

The solution is implemented using a <u>dynamic programming</u> approach, which utilizes iteration and optimal substructure properties

days ago.

cooldown).

common in such problems.

 f0 is initialized to 0, representing the profit with no stock on hand at the start. o f1 is set to -prices[0], accounting for the cost of buying stock on the first day. • A temporary variable f will hold the previous value of fo during iteration, serving as a memory for the state of profits two

been set up). During each iteration, we perform two key updates to represent possible actions and their outcomes:

• Initialization: Before the loop begins, we prepare our initial state variables:

- o fo gets updated to max(fo, f1 + x), where x is the current day's stock price. This represents the maximum profit between
- ∘ f1 gets updated to max(f1, f x), which represents the maximum profit between keeping the stock obtained before (f1) or buying today (which requires the previous day's profit f minus the current price x; note this action is only permitted after a

not selling/buying anything on the current day (f0) and selling the stock bought at f1 price (therefore, f1 + x).

• Iteration: We begin iterating through the prices array from the second day onward (since the first day's decisions have already

- Data Structures: We use three integer variables f0, f1, and f, which change with each iteration to keep track of our decision impacts. No additional data structures are used, making the space complexity linear. • Pattern: The pattern applied here is reminiscent of state machine logic used in dynamic programming. Multiple states (fo and f1) are considered, with transitions based on conditions specified by the problem statement. The decision on each day depends on the state of the previous days (either one or two days back).
- algorithm completes after the last day in the input array. The return value is fo because it represents the maximum profit obtainable with the last action being rest or sale, aligned with the problem requirements. The algorithm's overall complexity is O(n), as it involves a single pass through the prices array, and the operations within each

iteration are constant time. This approach effectively balances the problem constraints and the need to make optimized decisions at

• Algorithm Completion: The loop continues to make decisions and update states based on the stock prices for each day. The

Example Walkthrough Let's consider a small example using the solution approach outlined above. Suppose we have the following stock prices over a series

of days: prices = [1, 2, 3, 0, 2]. Using the provided algorithm and dynamic programming approach, we'll calculate the maximum

• Day 0: Before the loop starts, let's initialize our variables. f0 is set to 0, because we haven't made any transaction yet.

profit possible.

• Day 1:

• Day 2:

• Day 4:

 Update f to the previous value of f0 which is 0. • Calculate f0 as max(f0, f1 + prices[1]) = max(0, -1 + 2) = 1. • Update f1 as max(f1, f - prices[1]) = max(-1, 0 - 2) = -1.

Update f to the previous value of f0 which is 1.

Update f to the previous value of f0 which is 2.

• Calculate f0 as max(f0, f1 + prices[3]) = max(2, -1 + 0) = 2.

• Calculate f0 as max(f0, f1 + prices[4]) = max(2, 2 + 2) = 4.

• Update f1 as max(f1, f - prices[4]) = max(2, 2 - 2) = 2.

○ At the end of Day 1, f0 is 1 and f1 is -1.

At the end of Day 2, f0 is 2 and f1 is −1.

each step, leading to an efficient and intuitive solution.

• Calculate f0 as max(f0, f1 + prices[2]) = max(1, -1 + 3) = 2. • Update f1 as max(f1, f - prices[2]) = max(-1, 1 - 3) = -1.

∘ f1 is set to -prices[0] which is -1, because we bought one share of stock at the price of 1.

- Day 3:
- Update f1 as max(f1, f prices[3]) = max(-1, 2 0) = 2. At the end of Day 3, f0 is 2 and f1 is 2.
- At the end of Day 4, f0 is 4 and f1 is 2. After iterating through all the days, our algorithm concludes and the maximum profit that we can yield from the given prices is stored in f0, which is 4. This means the best strategy would have resulted in a total profit of 4, considering all the buy-and-sell transactions

and the compulsory cooldown period after each sale.

# Initialize variables:

for current\_price in prices[1:]:

sell\_profit,

return sell\_profit

28 # profit = sol.maxProfit([7,1,5,3,6,4])

int noStockProfit = 0;

for (int i = 1; i < prices.size(); ++i) {</pre>

holdProfit = noStockProfit;

int holdProfit = 0;

Update f to the previous value of f0 which is 2.

Python Solution from typing import List class Solution: def maxProfit(self, prices: List[int]) -> int:

# freeze\_profit (f) - profit of the day before cooldown

freeze\_profit, sell\_profit, hold\_profit = 0, 0, -prices[0]

# Iterate through the stock prices, starting from the second day

# freeze\_profit remains as the sell\_profit from the previous day

// fl: the max profit we can have at this state if we hold one stock

int oneStockProfit = -prices[0]; // Assume we bought the first stock

// Loop through the list of prices starting from the second price

// Calculate the max profit if we don't hold a stock today

// Calculate the max profit if we hold one stock today

// we buy a new stock today (holdProfit - prices[i]).

// either we did not hold a stock yesterday (noStockProfit) or

// either we were already holding a stock (oneStockProfit) or

oneStockProfit = max(oneStockProfit, holdProfit - prices[i]);

// Update noStockProfit to the new calculated noStockProfit

// we sold the stock we were holding (oneStockProfit + prices[i]).

int newNoStockProfit = max(noStockProfit, oneStockProfit + prices[i]);

// Update holdProfit to the previous noStockProfit at the end of the day

// holdProfit: stores the previous f0 state to calculate the new f1 state

# sell\_profit (f0) - profit after selling the stock

freeze\_profit, sell\_profit, hold\_profit = (

# Update profits for the current day

19 max(sell\_profit, hold\_profit + current\_price), 20 max(hold\_profit, freeze\_profit - current\_price) 21 22 23 # The maximum profit will be after all trades are done, which means no stock is being held, hence sell\_profit

# sell\_profit is the maximum of either keeping the previous sell\_profit or selling stock today (hold\_profit + current\_pri

# hold\_profit is the max of either keeping the stock bought previously or buying new stock after cooldown (freeze\_profit

# hold\_profit (f1) - profit after buying the stock or holding onto the stock bought previously

29 # print(profit) # Output: 5

26 # Example usage:

27 # sol = Solution()

# Time and Space Complexity

stock prices, where prices is a list of stock prices.

## **Time Complexity** The time complexity of the code is driven by a single loop that iterates through the list of stock prices once (excluding the first price

which is used for initial setup). Inside the loop, the code performs a fixed number of comparisons and arithmetic operations for each price. Because these operations occur within the loop and their number does not depend on the size of prices, they constitute constant-time operations. Therefore, the time complexity is determined solely by the number of iterations, which is n - 1, where n is the length of prices.

The given Python code defines a method maxProfit designed to find the maximum profit that can be achieved from a sequence of

Considering big O notation, which focuses on the upper limit of performance as the input size grows, the time complexity of this algorithm is O(n).

**Space Complexity** The space complexity is assessed based on the additional memory used by the algorithm as a function of the input size. In this code, only a fixed number of variables f, f0, and f1 are used, regardless of the size of the input list prices. There is no use of any

additional data structures that would grow with the input size. Thus, the space complexity of the algorithm is 0(1), denoting constant space usage.
