# 1151. Minimum Swaps to Group All 1's Together

**Problem Description** 

**Leetcode Link** 

together in the array. The 1s can be placed at any location within the array, but they must be consecutive (i.e., no 0s in between them). By swap, we mean taking two adjacent elements and exchanging their positions. This problem is asking us to perform a series of swaps to bring all 1s together and minimize the number of swaps made in this process.

Given a binary array data, which consists only of 0s and 1s, the task is to find the minimum number of swaps required to group all 1s

another 1 if there is a 0 in between without first swapping that 0 out of the way. The goal is to find the optimal strategy so that you minimize the total number of swaps required.

To provide more clarity, a swap can only be made with two adjacent elements, which means you cannot take a 1 and swap it with

#### The intuition behind the solution involves sliding window and greedy strategies.

Intuition

segment containing the maximum number of 1s. Why? Because the fewer the 0s in this segment, the fewer swaps are needed for

grouping 1s together. The size of this segment (i.e., the window) will be equal to the total number of 1s in the array, let's call it k. So, the window will be a subarray of length k. The number of swaps required will then be the number of 0s in our optimal segment because each of these 0s will need to be swapped with a 1 outside the segment.

To find the optimal segment, we consider all possible segments of length k by using a sliding window through the array. For each

Firstly, we must realize that we are grouping all 1s together. Instead of focusing on the 0s we need to move, we concentrate on the

segment, we calculate how many 1s it contains — this tells us indirectly the number of 0s since the window's length is fixed. We want the segment with the maximum number of 1s because that would mean the minimum number of 0s, and thus the minimum number of

swaps needed. The code sets up this sliding window starting from the beginning of the array and initializes a variable mx with the number of 1s in this first window. It then moves the window across the array one element at a time, calculating the count of 1s by adding data[i] and subtracting data[i - k] which keeps the window size constant. If the count is greater than mx, it updates mx. At last, because k

the optimal segment, which is k - mx. Solution Approach The solution leverages the sliding window technique to efficiently compute the number of 1s in each window of size k, where k is the total number of 1s in the input array data.

is the total number of 1s which should be grouped together, the minimum number of swaps needed is equal to the number of 0s in

### 1. Counting 1s in the Array: We start by counting the number of 1s in the entire array using data.count(1), which will determine

Here is a walkthrough of the implementation steps:

the size of our sliding window. This count is stored in the variable k.

most twice - once when it enters the window and once when it leaves.

us the minimum number of 0s to swap with.

the window (0), so t remains 2. mx is still 2.

the window (1), so t becomes 1. mx remains 2.

of 1s we found together in all windows of size k=4 was 2.

current\_count = sum(data[:total\_ones])

for i in range(total\_ones, len(data)):

max\_ones = max(max\_ones, current\_count)

28 # print(solution.min\_swaps([1, 0, 1, 0, 1, 0, 0, 1, 1, 0, 1])) # Output: 3

maxOnesInWindow = Math.max(maxOnesInWindow, onesInCurrentWindow);

// The minimum number of swaps is the size of the window 'k' minus

// the maximum number of 1's that can be placed in a window

1 #include <vector> // Include the vector header for using std::vector

#include <algorithm> // Include the algorithm header for the std::max function

max\_ones = current\_count

return total\_ones - max\_ones

// has more 1's

return numOfOnes - maxOnesInWindow;

keep track of the maximum number of 1s found in any window, which is initially equal to t.

Let's go through the solution approach with a small example using the given binary array data:

2. Initial Window Setup: We set up the initial window by calculating the sum of the first k elements in the array (sum(data[:k])). The result gives us the number of 1s in the initial window, which is stored in the variable t. We also introduce a variable mx to

the element that leaves the window (data[i - k]) from t. 4. Updating the Maximum 1s Count: After adjusting t for the new window position, we check if the updated count is greater than the current maximum (mx). If it is, we update mx to this new value.

3. Sliding Window Movement: We then iterate through the array starting from the kth element. In each iteration, we simulate the

sliding of the window by one element to the right. We add the new element that enters the window (data[i]) to t and subtract

total number of 1s (k). The result (k - mx) represents the minimum number of swaps required to group all 1s because it's the number of 0s in the window that contains the maximum number of 1s. The time complexity of this solution is O(n), where n is the length of the input array. This is because each element in data is visited at

5. Calculating the Result: Once we have completed sliding through the array, we subtract the maximum 1s count (mx) from the

Example Walkthrough

1 0 1 0 1 0 1 0 0 1

1. Counting 1s in the Array: There are 4 1s in the array, so k = 4. We are looking for a contiguous segment of size k which will give

2. Initial Window Setup: We set up the initial window over the first 4 elements: 0 1 0 1. The count of 1s in this window is t = 2.

## We also initialize mx with the value of t, so mx = 2.

3. Sliding Window Movement:

Example data array:

the window (1), so t remains 2. mx is still 2. Move the window one step right to 1 0 1 0. Update t by adding the new element (0) and subtracting the element that left

Move the window one step right to 0 1 0 1. Update t by adding the new element (1) and subtracting the element that left

Move the window one step right to 1 0 1 0. Update t by adding the new element (0) which is entering the window and

subtracting the first element of the previous window (0), so t remains 2. mx does not change.

• Finally, move the window to the last possible position 1 0 0 1. Update t by adding the new element (1) and subtracting the element that left the window (0), t becomes 2. mx remains 2 since it's not less than 2.

4. Updating the Maximum 1s Count: During the above window movements, mx never increased above 2, so the maximum number

5. Calculating the Result: The minimum number of swaps required is k - mx = 4 - 2 = 2. So, we need at least 2 swaps to group

keeping track of the maximum. The final answer is derived from the size of our window minus this maximum value, giving the

# Initialize the maximum count of 1s found so far to the current count of the initial window.

# Iterate over the array starting from the end of the first window to the end of the array.

Move the window one step right to 0 1 0 0. Update t by adding the new element (0) and subtracting the element that left

- all 1s together in this example. In summary, using the sliding window technique makes us move across the array, updating the number of 1s in each window and
  - class Solution: def min\_swaps(self, data: List[int]) -> int: # Calculate the total number of 1s needed to form a continuous subarray. total\_ones = data.count(1) # Initialize the current count of 1s in the first window of size 'total\_ones'.

# The minimum number of swaps equals the number of 0s in the largest window of 1s (size of the window - max count of 1s).

# Include the next element in the window and remove the trailing element to slide the window forward. 16 current\_count += data[i] current\_count -= data[i - total\_ones] 19 20 # Update the maximum count of 1s if the current window has more 1s than any previous ones.

24 }

// and subtracting the element that's no longer in the window. 14 currentOnes += data[i] - data[i - totalOnes]; 15 16 // Update the maximum number of 1s in any window if the current window has more. maxOnesInWindow = Math.max(maxOnesInWindow, currentOnes); // The minimum number of swaps equals the window size minus the maximum number 21

// Track the maximum number of 1s found in any window of size k (to minimize swaps).

// of 1s in any window, which tells us how many 0s need to be swapped out.

// Update the count of 1s in the current window by adding the new incoming element

operations: 1. Counting the number of 1s in the data array using data.count(1). This operation goes through each element of the array,

The time complexity of the minSwaps function is O(n), where n is the length of the data array. The function comprises of two main

element and subtracts the element k positions before it. The loop runs n - k times. Since addition and subtraction are constant time operations, the time complexity of the loop is O(n - k). Since k is less than or equal to n, the loop still implies an O(n) time complexity.

2. The sliding window loop, which starts from index k up to the end of the array. In each iteration, the function adds the current

Combining both parts, the overall time complexity is O(n) + O(n) = O(n).

**Space Complexity:** The space complexity of this function is 0(1). It uses a fixed number of variables (k, t, and mx) that do not depend on the size of the input. No additional data structures that scale with the size of the input are used. The variables i used for iteration and the space required for data.count(1) are also constant and do not contribute to the space complexity beyond 0(1).
