2517. Maximum Tastiness of Candy Basket **Binary Search** Medium Array Sorting

Leetcode Link

In this problem, you have an array called price where each element price[i] represents the price of the i-th candy. There's also a

Problem Description

You need to form a basket with k distinct candies such that the difference between the lowest and highest price in the basket (referred to as the basket's "tastiness") is as large as possible. However, tastiness is actually defined as the *smallest* absolute

positive integer k, which denotes the number of candies in a basket. Note that all candies in a basket must have distinct prices.

difference you can find among any two prices in the basket. Your task is to determine the maximum tastiness that a basket can achieve and return that value.

Intuition

(tastiness). The key idea is to find the maximum value for the smallest possible price difference in the basket—this is the tastiness. We want to ensure that we can find k distinct candies with at least this tastiness value.

Here is how we approach the solution: 1. Since the candies must be distinct, we first sort the price array. This will help us easily identify distinct candies and ensure that we can check intervals properly for tastiness.

2. We then apply binary search on the potential values of tastiness (the smallest price difference). The lower bound (1) is 0 (when

To solve this problem, we use a binary search approach due to its sorted nature and the need to maximize a specific smallest value

two candies have the same price, which is not allowed, but serves as our minimum starting point), and the upper bound (r) is the largest possible price difference (the price of the most expensive candy minus the price of the cheapest one).

6. Finally, we return 1 as the answer, which now holds the largest minimum tastiness possible.

to the basket while maintaining the condition related to x.

True or False based on whether we can have k candies or not.

we're using (1 + r + 1), it ensures proper rounding).

- 3. The function check takes a value x and determines if it's possible to select k distinct candies such that each pair of selected candies has at least x difference in their prices. We iterate through the sorted prices, counting how many candies can be added
- 4. In the binary search loop, we check the middle of our current range (mid) to see if there's a valid basket with tastiness equal to mid. If it's possible, we know we can attempt higher values for tastiness, so we move our lower bound 1 up to mid. If it's not possible, we know we need to reduce our expectations of tastiness, so we adjust the upper bound r to mid - 1.
- 5. When the loop ends, the range has narrowed down to the highest value of 1 that satisfies our conditions, which is the maximum possible tastiness for the basket.
- This strategy works because we leverage the sorted nature of the array and use binary search to efficiently converge on the largest minimum tastiness value achievable.
- Let's break down the implementation step-by-step to understand how the given solution uses binary search to find the tastiness of a basket:

1. Sorting the Prices: The price array is sorted at the very beginning of the solution. Sorting is crucial because for binary search to work, the elements need to be in a sorted order, and this step also supports checking for distinct candies efficiently.

2. Binary Search Setup: Two pointers 1 and r are initialized to frame the search space for the maximum tastiness. 1 is set to 0

because tastiness cannot be negative, and r is set to the difference between the highest and lowest price, i.e., price[-1] -

3. The check Function: The check function is the heart of the binary search implementation. It takes a tastiness value x and checks if there are at least k candies in the sorted price list where the adjacent selected candies have at least x difference between

size of the input array.

Example Walkthrough

for the highest possible tastiness.

price[0].

Solution Approach

4. Executing the Binary Search: We use a while loop to perform the binary search between 1 and r. Inside the loop, we calculate mid, which is the midpoint between 1 and r, using (1 + r + 1) >> 1 (bitwise shift right is equivalent to division by 2, but since

them. The function keeps a count (cnt) of how many candies can be a part of the basket with the given tastiness and returns

mid - 1. 6. Narrowing Down and Result: The loop continues until 1 < r is no longer true, meaning 1 and r converge to the maximum value

7. Returning the Solution: Once the loop is concluded, 1 is the required maximum tastiness value, and it's returned as the solution.

By implementing binary search, the solution efficiently navigates through the potential tastiness values to find the optimal solution.

The code is optimized to reduce the number of iterations needed to pinpoint the maximum tastiness, which is key given the potential

that satisfies the condition that k distinct candies have at least 1 difference between each other in price.

1. Sorting the Prices: Our array price is already sorted ([1, 5, 9, 14]), so this step is complete.

1) >> 1 = 7. We need to see if it's possible to pick 2 candies at least 7 units apart in price.

at least 7). Since the check function returned True, we move the lower bound up: now, l = 7.

5. Decision Making: With the mid value, we call the check function. If check(mid) returns True, it means that mid is a valid tastiness

check(mid) returns False, we know that mid is too high of a tastiness value to maintain k distinct candies, so we bring r down to

value for a basket with k distinct candies, so we can attempt to find an even larger tastiness value by adjusting 1 to mid. If

To illustrate the solution approach, let's use a small example: Suppose we have an array of candy prices given by price = [1, 5, 9, 14] and we want to form a basket with k = 2 candies, aiming

3. The check Function: We would define our check function, which would check if we can select k candies with at least x difference in price between any two of them. 4. Executing the Binary Search: With l = 0 and r = 13, we proceed with binary search. The first mid value to check is (0 + 13 + 13)

5. **Decision Making:** We call check(7). Starting with the cheapest candy, we can choose price[0] = 1. Then, we see that price[2]

= 9, which is 8 units apart from price[0]. Thus, we found a valid basket, [1, 9], with tastiness 7 (since 9 - 1 = 8 and we needed

2. Binary Search Setup: We set l = 0 and r = 14 - 1 = 13, the range within which we'll look for the maximum tastiness value.

The next mid is (7 + 13 + 1) >> 1 = 10. For check(10), we can start again by choosing price[0] = 1. Then, we find that there is no other candy price at least 10 units apart from 1 in the given prices. Hence, check(10) returns False, and we lower the upper

constraints with k distinct candies.

bound: now, r = 10 - 1 = 9.

We continue the binary search. With l = 7 and r = 9, mid = (7 + 9 + 1) >> 1 = 8. A check(8) call is True with the basket [1,

def maximumTastiness(self, prices: List[int], target_count: int) -> int:

at least the minimum distance, select this cake

Initialize binary search boundaries for the minimum distance

Perform binary search to find the maximum minimum distance

Otherwise, continue with the left half

The maximum minimum distance will be `left` after binary search ends

* Finds the maximum difference between the tastiness values of any two selected items.

* @param prices Array representing the tastiness values of different items.

* @return The maximum difference possible between the tastiness values.

Initialize counter for number of cakes and the previous cake's price

45
Time and Space Complexity
The given Python code snippet is designed to find the maximum minimum distance (tastiness) between any two selected elements
in the array price, while picking exactly k elements. It leverages binary search to find the solution efficiently. Here is the
computational complexity analysis:
Time Complexity
```

1. price.sort(): The sorting of the input list has a time complexity of O(n * log n) since Python uses Timsort (a hybrid sorting algorithm derived from merge sort and insertion sort) for its sorting.

elements in the sorted price list. Because we are halving our search space in each iteration, the number of iterations needed is proportional to the logarithm of the range. 3. Inside the binary search loop, the check function is called. It iterates over the entire price list in O(n) time, as it potentially goes

2. The binary search loop: The while loop runs in O(log m) time, where m is the difference between the maximum and minimum

The overall time complexity of the code is 0(n * log m), where n is the number of elements in the input list price, and m is the range

of possible tastiness values, which is the difference between the minimum and maximum values in price.

through all elements to count how many valid selections of tastiness can be made.

1. The list is sorted in-place, not requiring additional space relative to the input size.

- Combining the sorting step and the binary search steps, the time complexity becomes 0(n * log n) + 0(log m) * 0(n), which simplifies to 0(n * log n) + 0(n * log m) since 0(n * log m) dominates 0(n * log n). Thus, the final time complexity is 0(n * log n)m).
- **Space Complexity** The space complexity of the code is 0(1).

2. The check function uses constant space, only needing additional variables to store the count (cnt), previous selected element

(pre), and iteratively checking each element (cur). 3. Since there are no additional data structures that grow with the input size, the space complexity is maintained at a constant level.

Therefore, the space complexity is 0(1), indicating that the space required does not increase with the size of the input list price.
