1312. Minimum Insertion Steps to Make a String Palindrome

Problem Description

Dynamic Programming

The task is to make a given string s a palindrome by inserting any number of characters at any position in the string. The objective is

Leetcode Link

to achieve this with the minimum number of insertions possible. A palindrome is a word, number, phrase, or other sequences of characters that reads the same forward and backward, ignoring spaces, punctuation, and capitalization.

s.

Intuition

upon those to arrive at the final answer. We can define our subproblem as f(i, j), which is the minimum number of insertions to make the substring s[i...j] a palindrome. Therefore, f(0, n-1) (where n is the length of the string) will eventually be our answer for the whole string s.

subproblems. These subproblems involve finding the minimum number of insertions for all substrings of the given string and building

To solve this problem, we can use dynamic programming. The core idea is to build a solution using the answers to smaller

If the characters at the position i and j are the same, no insertion is needed, and f(i, j) will be the same as f(i+1, j-1) — the number of insertions needed for the substring without these two matching characters. However, if they do not match, we have to do

an insertion either at the beginning or the end of the substring. This means we have two options: either insert a character matching

s[j] before i or insert a character matching s[i] after j. Therefore, we'll take the minimum of f(i+1, j) and f(i, j-1) and add one (for the insertion we've made). We do this for all possible substrings starting from the end of the string and moving backward, which finally gives us the minimum number of insertions needed to make the entire string a palindrome. The Python solution provided implements this dynamic programming approach. It utilizes a 2D array f where f[i][j] holds the minimum number of insertions needed for the substring s[i...j]. We iterate through the string in reverse, gradually building up the solution for the entire string and returning f[0][-1], which represents the minimum number of insertions needed for the whole string

Solution Approach The solution to this problem applies dynamic programming because a direct approach would involve checking every possible

insertion, leading to an inefficient exploration of the problem space. Dynamic programming, however, allows us to solve the problem

more efficiently by breaking it down into overlapping subproblems and building up the answer. Here's a step-by-step explanation of the dynamic programming solution provided in the Reference Solution Approach:

insertions required to make the substring s[i...j] a palindrome. 2. We initialize our dp array f with zeros because if i equals j, the substring is already a palindrome, and no insertions are needed.

1. We use a 2D array f with dimensions n by n, where n is the length of the string s. f[i][j] will represent the minimum number of

at n-2 is that the last character does not need any insertions to become a palindrome; it already is one on its own.

3. The main process occurs in a nested loop. We first iterate over i in reverse, starting from n-2 down to 0. The reason for starting

- 4. For each i, we then iterate over j from i+1 to n-1. This loop considers all substrings that start at index i and end at index j.
- ∘ If s[i] is equal to s[j], no additional insertions are needed to pair them up, so f[i][j] is set equal to f[i+1][j-1] (the minimum insertions needed for the inside substring).

5. Inside the nested loops, we check if the characters at index i and j are the same.

subproblems considering one side extended), plus one for the current insertion.

whole string, because it refers to the subproblem considering the entire string s[0...n-1].

complexity is a significant improvement over any naive approach.

align s[j] with a character to the left. Therefore, f[i][j] is the minimum of f[i+1][j] and f[i][j-1] (the solutions to

6. At the completion of the loops, f[0] [-1] contains the answer. It represents the minimum number of insertions needed for the

By using dynamic programming, we avoid re-computing solutions to subproblems, which makes for an efficient solution. The

0(n^2) as well for storing the dp array. While the space complexity could be a concern for very long strings, the quadratic time

o If s[i] is not equal to s[j], we must insert a character. We can choose to align s[i] with some character to the right or to

Reference Solution Approach leverages this overlapping of subproblems and optimal substructure properties common in dynamic programming problems. This algorithm has a time complexity of 0(n^2) due to the nested for loops iterating over all substrings, and a space complexity of

Let's consider a short example with the string s = "abca". We want to find the minimum number of insertions required to make s a palindrome. 1. Initialize a 2D array f with dimensions 4×4, with all values set to 0, since the length of the string s is 4.

2. Fill in the dp array f starting from i = 2 down to 0. We need to loop from j = i+1 to 3. We ignore cases where i == j because

3: s[2] = "c", s[3] = "a". They do not match, so we need one insertion. We take the minimum from

Example Walkthrough

3. Sta	art	with	1 i =	2 ar	nd j
f[2+	1] [3]	anc	f [2] [3–:
		0	1	2	3
()	0			
1	ı		0		
	,			_	1

those are already palindromes.

3 0 4. Move to i = 1 and j = 2: s[1] = "b", s[2] = "c". They do not match, so we take the minimum of f[1+1][2] and f[1][2-1], with

an extra insertion. Since f[2][2] and f[1][1] are 0, we set f[1][2] to 1.

f[1][3-1], which are 1 and 1 at this point, plus one for the insertion; we get f[1][3] = 2.

7. For i = 0, j = 2, we take the minimum of f[1][2] and f[0][1]. Both are 1 currently, so f[0][2] = 2.

8. Finally, for i = 0, j = 3, we compare s[0] with s[3], which are the same. So, we set f[0][3] to f[1][2], which is 1.

6. Now for i = 0 and j = 1: s[0] = "a", s[1] = "b". They're different, so we set f[0][1] to the minimum of f[0+1][1] or f[0][1-1]plus 1, which equals 1.

5. For i = 1 and j = 3, compare s[1] to s[3], which are "b" and "a". They're different, so f[1][3] is the minimum of f[1+1][3] and

- 2 The top right cell f[0] [3] gives us the minimum number of insertions needed, which is 1. In this case, we can insert a "b" at the end
- This example demonstrates the procedure described in the solution approach, illustrating the steps taken to fill the dp array and find the minimum number of insertions to make the string s a palindrome.
- # minimum number of insertions needed to make s[i...j] a palindrome dp = [[0] * length for _ in range(length)] 8 9 10 # Loop backwards through the string so that we can solve # for all the smaller subproblems first 11

length = len(s)

The final dp array f looks like this:

of the string to get "abcba", which is a palindrome.

def minInsertions(self, s: str) -> int:

for i in range(length -2, -1, -1):

if s[i] == s[j]:

else:

return dp[0][-1]

public int minInsertions(String s) {

Java Solution

class Solution {

for j in range(i + 1, length):

contributes to a palindrome

dp[i][j] = dp[i + 1][j - 1]

for the whole string, which is what we return.

dp (Dynamic Programming) table where dp[i][j] will hold the

If the characters at position i and j are the same,

no more insertions are required here since it already

If the characters are different, we need one more

or at the end of the substring. We choose the option

that requires fewer insertions, hence the min function.

insertion. We can insert either at the beginning

dp[i][j] = min(dp[i + 1][j], dp[i][j - 1]) + 1

The top-right corner of the dp table contains the answer

Length of the input string

```
int length = s.length();
           int[][] dp = new int[length][length]; // Using dp array to store minimum insertion results
           // Iterating in reverse order from second last character to the beginning
           for (int i = length - 2; i >= 0; --i) {
               // Iterating from the character just after i up to the end of the string
               for (int j = i + 1; j < length; ++j) {
                   // If the characters at i and j match, no insertion is needed; carry over the value from the previous subproblem
                   if (s.charAt(i) == s.charAt(j)) {
11
                       dp[i][j] = dp[i + 1][j - 1];
12
                   } else {
13
                       // If the characters do not match, find the minimum insertion from the two adjacent subproblems and add 1
14
                       dp[i][j] = Math.min(dp[i + 1][j], dp[i][j - 1]) + 1;

// No insertion needed if characters at startIdx and endIdx are the same,

dp[startIdx][endIdx] = dp[startIdx + 1][endIdx - 1];

// we just take the value from the diagonal entry before the next iteration

for (int endIdx = startIdx + 1; endIdx < n; ++endIdx) { // End index ranges from the character after startIdx to the end

23 // which is stored in the top right corner of the DP table. return dp[0][n - 1]; 24 25 } 26

Time and Space Complexity

} else {

It uses dynamic programming to accomplish this task. The analysis of time and space complexity is as follows: **Time Complexity:**

The time complexity of the code is $0(n^2)$, where n is the length of the input string s. This is because there are two nested loops:

The given Python code snippet is designed to find the minimum number of insertions needed to make the input string a palindrome.

The outer loop runs backwards from n-2 to 0, which contributes to an 0(n) complexity.

Space Complexity:

The inner loop runs from i + 1 to n, which also contributes to 0(n) complexity when considered with the outer loop.

- Since each element f[i][j] of the DP matrix f is filled once and the amount of work done for each element is constant, the overall time complexity is the product of the two O(n) complexities.
- intermediate results of the dynamic programming algorithm.

The space complexity of the code is also $0(n^2)$. This is because a two-dimensional array f of size n * n is created to store

So, both the space and time complexity are quadratic in terms of the length of the input string.
