so that all monsters can be defeated in the least number of days possible.

Dynamic Programming

Array

Problem Description In this problem, you are tasked with defeating all the monsters in an array power, where power[i] represents the power level of the i-

Bit Manipulation

Hard

th monster. You start with 0 mana points, and each day, you gain more mana points. Initially, you gain 1 mana point per day, and each day this amount increases by 1 after you defeat a monster. However, you can only defeat a monster on a given day if your current mana points exceed or are equal to that monster's power. If

Bitmask

you defeat a monster, your mana points reset to 0, and the daily mana gain (gain) increases by 1. The goal is to find the minimum number of days required to defeat all monsters in the array. To put it simply, the problem asks you to optimize the order of defeating monsters while considering the growth of your mana points

Intuition

Since each day you can choose to defeat any monster whose power level is less than or equal to your current mana, there could be

The solution approach for this problem can be understood in terms of a depth-first search (DFS) through all possible scenarios.

multiple choices, and thus multiple possible futures, to consider.

Given that each time you defeat a monster, your mana resets, the number of days needed depends on the order in which you choose to defeat the monsters. Using a bit-mask to represent which monsters have been defeated, we can systematically explore each choice. A bit-mask is a binary representation where each bit corresponds to a monster; if the bit is 1, the monster is defeated, and if it's 0, the monster remains.

The function dfs (mask) explores all possible choices from the current state defined by mask. If all monsters are defeated (the base case), it returns of since no additional days are needed. Otherwise, for each undefeated monster, it calculates the days needed to defeat it plus the days from defeating the remaining monsters and takes the minimum over all these possibilities. The @cache decorator is utilized to memorize results of subproblems making the algorithm more efficient by avoiding redundant calculations. mask.bit_count() is used to count how many bits are set to 1 (how many monsters have been defeated) which

determines the day's gain. (v + cnt) // (cnt + 1) calculates the number of days needed to accumulate enough mana to defeat the monster i with power v. Essentially, this approach applies recursion to simulate the passage of days, defeat monsters, and track mana gain, recording the minimum days taken to reach the condition where all monsters are defeated.

The implementation employs a recursive function dfs (mask) to walk through all possible ways one could defeat the monsters. Here is the step-by-step explanation of the algorithm:

a monster. If the bit is set (1), the monster is already defeated; else (0), the monster is yet to be defeated.

is equal to the length of the power array. In this case, dfs returns 0 because no additional days are required.

1. Recursion and Bitmask: The primary technique used is recursion combined with bitmasking. Each bit in the mask corresponds to

2. Base Case: The base case for the recursion is when all monsters have been defeated, which is when the bit_count of the mask

3. Exploring Paths: For each undefeated monster (those bits that are 0), the algorithm explores what would happen if you were to

recalculated again if encountered in the future.

recalculating already known states.

4, 2].

Solution Approach

defeat this monster next. It does so by calculating the number of days needed to defeat the monster ((v + cnt) // (cnt + 1)) added to the result of a recursive call to dfs with the monster defeated (mask | (1 << i)). The calculation considers the current count of defeated monsters (cnt) to determine the daily gain in mana points.

4. Minimum Days: The dfs function looks for the minimum number of days across all such recursive calls for different monsters. The variable ans stores the minimum number of days found so far and is updated whenever a smaller value is found.

5. Memoization: The algorithm uses memoization with the @cache decorator to store results of subproblems. This means that once

the number of days required to defeat a certain set of monsters (i.e., a particular mask) has been calculated, it won't be

7. The Initial Recursive Call: The function dfs (0) kicks off the recursion with all monsters undefeated.

6. Inf: The value inf from the Python math module (which represents "infinity") is used to initialize the ans variable. This ensures that the first comparison will always favor the first actual computed number of days over inf.

In summary, this is a classic brute-force search with optimization. The bitmask acts as a state representation for the set of monsters

defeated, and the minimum number of days is computed recursively with memoization to speed up the search process by not

- Example Walkthrough To illustrate the solution approach, let's consider an example. Suppose we have the following array of monster powers: power = [2,
- Day 1: We start with mana points and a gain of 1 mana point per day. We cannot defeat any monsters on day 1 because our mana is less than the power of any monster.

Day 2: We now have 1 (from Day 1) + 2 mana (since our gain increases daily) = 3 mana points total. We can defeat the first or the third monster (both with power 2), but not the second (with power 4). Let's defeat the first monster. Our mana resets to 0, but now our mana gain increases to 2 mana points per day.

Day 3: No mana from previous days since it reset, so you only gain 2 mana points this day. With only 2 mana points, we cannot defeat

any remaining monsters, since the next weakest has a power of 2 and we would need to start the day with at least 3 mana points to

Day 4: We carry over 2 mana points from Day 3 and gain 3 more (since our gain increases daily), giving us 5 mana points total. Now

defeat it (2 required + 1 since we have already defeated one monster, which is our additional mana gain per day).

Mask 2: 011, indicating that the first and third monsters are defeated, and only one monster, with power 4, is left.

we can defeat either the second or third monster. Let's choose the third monster. Our mana resets again.

Day 6: We gain 3 mana points.

Mask 3: 111. This means all monsters are defeated and the recursion base case is met.

This means we have three monsters with power levels 2, 4, and 2, respectively.

Mask 1: 001, meaning the first monster has been defeated, and two are left.

Day 7: We gain 4 mana points (since we defeated 2 monsters already, our gain is 2 and increases daily by 1), totaling 7 mana points, and now we can defeat the second monster with power 4.

To calculate the minimum number of days needed, we must consider all the permutation ways to defeat the monsters, which means

not only the path we walked through above. The algorithm does just that, by exploring all possibilities and caching the results for

Each of these calls will traverse further with their respective masks, accounting for the increasing mana gain and resetting after each defeat. In this simple example, it took us 7 days, but in a different order of defeating monsters, or a different power array, it might

1 dfs(0) -> minimum of {dfs(001), dfs(010), dfs(100)} -- these represent defeating each monster first.

efficiency. We end up with:

At the end of day 7, we have defeated all monsters.

Day 5: We start again with 0 mana.

Time and Space Complexity
```

The given Python code defines a function minimumTime which finds the minimum time required to reduce a given list of powers to

zero by deactivating machines in sequence, with the speed of deactivation increasing with each machine that is turned off.

The time complexity of the code can be determined by analyzing the dfs function, which is a depth-first search with memoization. The recursion explores each possible state represented by mask, which has a length of n where n is the number of elements in power. There are 2ⁿ possible states given that each element can be either active (1) or inactive (0). For every state, the function iterates

over all n elements to check which machines can be turned off next. Therefore, the total number of operations is $0(n * 2^n)$. Memoization is used to ensure that each state is computed only once. This is important because without memoization, the algorithm would have to recompute the same states exponentially more times. With memoization, each state's result is stored and reused, so the total number of distinct function calls matches the number of distinct states, which is 2^n.

complexity, the recursion stack contributes O(n). However, as the space used for memoization dominates the space required for the call stack as n grows, the overall space

The space complexity is determined by the space required for memoization and the recursion call stack. The memoization stores

results for each of the 2ⁿ possible states, so the space complexity for memoization is 0(2ⁿ).

complexity is O(2^n) for storing the results of each of the unique states.

The recursion stack's maximum depth would be n, since it represents turning off each machine exactly once. Thus, in terms of space
