1302. Deepest Leaves Sum

Depth-First Search Breadth-First Search Binary Tree

Problem Description

Medium

that reside in the deepest leaves of the tree. To clarify, the deepest leaves are the nodes at the bottom most level of the tree, which have no children.

The problem presents us with a binary tree, where each node contains an integer value. Our task is to find the sum of the values

Intuition The intuition behind the solution is to traverse the entire tree to find the deepest leaves and accumulate their values. We can

approach this problem using either <u>Depth-First Search</u> (DFS) or <u>Breadth-First Search</u> (BFS). DFS would involve a recursive function that keeps track of the current level and compares it against the maximum level found so

far. If the node being visited is a leaf and is at the deepest level seen so far, its value is added to the running sum. However, the provided solution utilizes BFS, which is a suitable approach for this type of problem because BFS explores the tree

level by level. We use a queue to keep track of nodes to visit and proceed through each level of the tree one by one. As we traverse and exhaust all nodes on a particular level, we can be confident that eventually, we will reach the deepest level. By summing all values at that final level, we get the sum of all the deepest leaves. We can implement BFS in Python using a queue (in this case, a deque for efficiency reasons). We initiate the queue with the root

node, and in each iteration, we process all nodes at the current level (queue size determines the level width). For each node, we

add its value to a sum accumulator and extend the queue with its children, if any. When the loop ends, the sum accumulator

contains the sum of the values at the deepest level, which is the final answer we want to return.

Solution Approach The solution uses the Breadth-First Search (BFS) pattern to solve the problem. BFS is ideal for this problem since it processes nodes level by level. In this approach, the algorithm makes use of a deque, which is a double-ended queue that allows for efficient addition and removal of elements from both ends.

Example Walkthrough

1. Initialize a deque with the root of the binary tree. 2. Initiate a loop that runs as long as there are nodes present in the deque. 3. Reset the sum accumulator ans to 0 at the start of each level. 4. Determine the number of nodes present at the current level by checking the length of the deque.

8. Check if the current node has a right child, if so, append it to the right side of the deque. 9. At the end of the level, all node values will have been added to ans, we then proceed to the next level (if any).

7. Check if the current node has a left child, if so, append it to the right side of the deque.

5. For each node of the current level, pop it from the left side of the deque.

6. Add the value of the current node to the accumulator ans.

Here's a step-by-step breakdown of the algorithm incorporated in the solution:

- 10. Once the loop exits, it means we have visited all levels. The last accumulated sum stored in ans is the sum of all the values of the deepest leaves in the binary tree.
- In terms of algorithmic efficiency, at each level n, all n nodes are processed, and each node is added to the queue once. This

Let's take an example binary tree to walk through the BFS solution approach.

- results in an O(N) time complexity, where N is the number of nodes in the binary tree. The space complexity is O(N) in the worst case, when the tree is complete, and the bottom level is full (half of the nodes are on the last level).

Now we apply the BFS algorithm step-by-step: We initialize a deque with the root of the binary tree. In this case, the root is the node with value 1. There's a node in the deque (the root), so we begin the loop.

We check for the left and right children of node 1. Both exist, so we append them to the right side of the deque. The deque

At the fourth level, we process the final nodes 7, 8, and 9, add their values to ans, which is now 7 + 8 + 9 = 24, and since

By following these steps, applying BFS allowed us to efficiently find the sum of the deepest leaves in the binary tree for our

As the deque is now empty, the loop exits. At this point, ans holds the sum of all the deepest leaf nodes, which is 24. This sum

Moving to the second level, we reset ans to 0. The deque has 2 nodes, so we will process both nodes 2 and 3.

Continuing to the third level, we reset ans to 0 again. The deque has 3 nodes, so it represents the third level.

Determine the number of nodes present at the current level. Initially, this is 1 since we start with just the root. We pop the node with value 1 from the left side of the deque and add its value to ans. ans now becomes 1.

now holds nodes 2 and 3.

4 + 5 + 6 = 15 and the deque holds 7, 8, and 9.

there are no more children, the deque becomes empty.

from collections import deque # Import deque for queue operations

def deepestLeavesSum(self, root: Optional[TreeNode]) -> int:

queue.append(node.left)

Initialize a queue with the root node

For both nodes, we remove them from the deque, add their values to ans, and add their children to the deque. After processing, ans is 2 + 3 = 5, and the deque now holds nodes 4, 5, and 6.

Reset the sum accumulator ans to 0. This holds the sum of values at the current level.

- We process nodes 4, 5, and 6 as before. We add their values to ans, and add their children to the deque. After this level, ans is 10.
- is the final answer, and it is the sum of the values of the deepest leaves in our example binary tree: 7, 8, and 9.
- Solution Implementation

example. The algorithm progresses level by level, and the running sum at the last level gives us our answer.

class TreeNode: def __init__(self, val=0, left=None, right=None): self.val = val self.left = left self.right = right

while queue: # Continue until the queue is empty level_sum = 0 # Sum of values at the current level level_count = len(queue) # Number of nodes at the current level # Iterate over all nodes at the current level for _ in range(level_count): node = queue.popleft() # Remove the node from the queue

level_sum += node.val # Add the node's value to the level sum

After the loop, level_sum contains the sum of values of the deepest leaves

If the node has a left child, add it to the queue

```
# If the node has a right child, add it to the queue
if node.right:
    queue.append(node.right)
```

Java

return level_sum

Python

class Solution:

The time complexity of the code is O(N), where N is the total number of nodes in the binary tree. This is because the algorithm

Time Complexity

return level_sum

Time and Space Complexity

uses a breadth-first search (BFS) approach to traverse each node in the tree exactly once to calculate the sum of the deepest leaves. **Space Complexity**

The space complexity of the code is O(N), where N is the maximum width of the tree or the maximum number of nodes at any level of the tree. In the worst-case scenario (e.g., a complete binary tree), this is essentially the number of nodes at the last level. The space complexity comes from the queue used to store nodes at each level while performing BFS.
