1526. Minimum Number of Increments on Subarrays to Form a Target Array

Monotonic Stack

Leetcode Link

Dynamic Programming

Problem Description

Greedy

Array

filled with zeros. The key objective is to transform the initial array into the target array. The only operation allowed to achieve this is to select a subarray from initial and increment each of its elements by one. The task is to determine the minimum number of such operations required to reach the target array configuration. It's also specified that the final answer will fit within a 32-bit integer, which means it won't be too huge for an int data type to store.

The problem presents an integer array called target. We also have an array of the same size as target, named initial, which is

differences between the heights (values) of adjacent elements in the target array.

To solve this problem, one needs to intuitively understand that the minimum number of operations needed is closely related to the

Intuition

each element in the target array represents the height at that particular position. Incrementing a subarray by 1 is like raising the

Intuition behind the solution arises from looking at the problem in terms of "height differences". Imagine a graph where the value of

Hard

ground level of a terrain from one point to another by one unit. To minimize operations, we should always try to raise the terrain in the largest possible steps rather than incrementing little by little. The first insight is that we'll have to increment the first element of initial to the first element of target for sure since there are no previous elements to consider, which accounts for target[0] operations.

Following that, we move through the target array and look at the difference between each pair of adjacent elements (b - a for elements a and b). Each time we encounter a rise in height (where b > a), we need additional operations equivalent to the height

difference to "build up" our terrain to that new height. If the height decreases or remains equal (b - a is less than or equal to 0), we do not need extra operations since we can imagine that the previous increments have already covered that height. By summing up all necessary height differences, we can get the total number of increments required. Therefore, the number of operations can be given by the first element of the target array plus the sum of all positive differences between successive

adjacent pairs of elements and calculate the sum of the positive differences. **Solution Approach** The solution to this problem utilizes a straightforward Greedy algorithm approach and Python's built-in functionality to generate

elements in the target array. The given Python function pairwise from the itertools library can be used here to generate the

Here's a brief walkthrough of the implementation:

adjacent pairs easily.

1. Initialization:

2. Iterating through the array:

the iterable target. 3. Calculating the Needed Operations: ∘ For each pair (a, b) obtained from the pairwise, we add to our operations count the difference (b - a) if b is greater than a. The expression max(0, b - a) ensures that we only consider positive differences, which represent an increase in value

We start by initializing the number of operations to the value of the first element in target, because the initial array is filled

with zeros, and we must at least increment the first element 'target[0]' times to match the first element of the target array.

We then iterate over the target array, comparing each element to its predecessor to find the difference between them. The

iteration of pairs is done using the pairwise function, which neatly returns a tuple containing pairs of adjacent elements from

initial[b]. If b is equal to or less than a, no extra operations are needed because we assume initial[a] is already at least at height a, so we can effectively "carry over" this height to initial[b].

5. Result:

from one element in target to the next.

4. Summation: We sum up all the extra operations needed for each increase in the array, adding it to our initial count of target [0] operations. The sum is computed using the built-in sum function, which takes an iterable.

• The final result is returned as the sum of the initial operations count and the accumulated extra operations needed. This sum

The rationale behind this is that whenever b is greater than a, we need additional operations to raise initial[a] to

 A List (target) to store the integer values we're working with, The Greedy algorithm pattern, where we take the optimal decision step-by-step based on the current and next element,

Python's built-in sum function to calculate the aggregate of operations needed,

The data structures and patterns used in this approach are quite simple and consist of:

- pairwise utility from the itertools library to iterate through the array in adjacent element pairs.
- in linear time, making it a very practical solution for this problem.

The beauty of this solution lies in its simplicity and efficiency. There are no complex data structures required, and the algorithm runs

represents the minimum number of operations required to form the target array from the initial array.

Let's walk through a small example to clearly understand how the solution approach works.

Start with operations count equal to the first element of target: operations = target[0] = 1.

 \circ Pair (3, 2): No increase (it's actually a decrease), so add 0: operations += max(0, 2 - 3) = 3.

Suppose we have a target array given as [1, 3, 2, 4]. Our goal is to transform an initial array from [0, 0, 0, 0] to match the target array using the fewest number of operations.

• The result is operations = 1 + 2 + 0 + 2 = 5. So, it takes a minimum of 5 operations to transform initial into target.

Next, we perform a third operation on the same subarray, resulting in [2, 2, 0, 0]. No operation is needed for the transition from 3

to 2, as the previous operations have already covered this. Finally, we perform two more operations from index 2 to index 3 to

increment the last two elements by 1 each time, resulting in [2, 3, 1, 1] and then [2, 3, 2, 2], and finally our target [1, 3, 2,

4. Summation:

5. Result:

2. Iterating through the array:

4]. Thus, a total of 5 operations were needed.

1. Initialization:

Example Walkthrough

 Generate pairs using pairwise: (1, 3), (3, 2), (2, 4). 3. Calculating the Needed Operations:

 \circ Pair (1, 3): Increase is 2, so add 2 to operations: operations += max(0, 3 - 1) = 3.

 \circ Pair (2, 4): Increase is 2, so add 2 to operations: operations += max(0, 4 - 2) = 5.

- We combine the counted operations to get the total.
- In this example, we increment the first element (index 0) of the initial array 1 time to match the first element of the target array, then we perform another operation on the subarray from index 0 to index 1 to increment both elements (making the array [1, 1, 0, 0]).

from itertools import pairwise # Python 3 function from the itertools module

The total number of operations to match the target array is returned

// Initialize minimum operations with the first element

// since that's the minimum number of operations needed

// Iterate through the array starting from the second element

* @param target Vector of integers representing the target array.

// Iterate through the target array starting from the second element.

// If the current target value is greater than the previous,

* @return The minimum number of operations required.

by 1. The function minNumberOperations does this by summing the differences between consecutive elements where the second

Time and Space Complexity

space complexity: Time Complexity:

The code provided calculates the minimum number of operations to form a target array where each operation increments a subarray

22 }

23

element is larger than the first, plus the value of the first element in the target array. Let's analyze both the time complexity and

Therefore, the overall time complexity of the code is O(n).

Space Complexity:

The function iterates once over the list of target elements using the pairwise utility to consider pairs of consecutive elements. The time complexity for this operation is O(n), where n is the length of the target array, because it goes through the list once. The pairwise utility itself, which is presumably a wrapper around a simple loop-like construct that yields successive pairs of elements, does not add any significant time overhead as it just creates a tuple of the current and next elements in the array.

expressions which yield one item at a time. The max function is applied in a generator expression, so it does not require additional space proportional to the input size.

The function is a one-liner without the use of additional data structures that depend on the size of the input. It relies on generator

The space complexity is not affected by the size of the input array, as the sum function processes the generator expression

iteratively. The pairwise utility is expected to yield one pair at a time and doesn't store the entire list of pairs in memory. As a result, the overall space complexity of the code is 0(1), reflecting constant space usage.
