2226. Maximum Candies Allocated to K Children

Problem Description

Medium Array

Binary Search

In this problem, you have an array candies, where each element represents a pile of candies (with index starting from 0). Each pile contains a certain number of candies denoted by candies [i]. The array gives you the flexibility to split any pile into smaller sub-piles but does not allow you to combine two different piles into one.

goal is to distribute the candies to k children in such a way that each child receives exactly the same number of candies.

However, each child can receive at most one pile (which can potentially be a sub-pile of one of the original piles), and it's possible that not all piles will be distributed.

The objective is to find the maximum number of candies that you can give to each child under these conditions.

To solve this problem, we need to determine the *maximum number of candies each child can get*. The key here is understanding

into smaller ones). However, we cannot always give more than x candies. So, our solution will likely involve finding the optimal x.

Additionally, you are given an integer k, which represents the number of children to whom the candies must be distributed. The

The objective is to find the maximum number of candies that you can give to each child under these conditions.

Intuition

that if we can give x candies to each child, then surely we can give any amount less than x candies as well (by dividing the piles

One way to approach this is through <u>binary search</u>. The minimum number of candies a child could get is 0 (if k is larger than the total number of candies available) and the maximum is the size of the largest pile in <u>candies</u>.

Using <u>binary search</u>, we can find the largest possible value for x in the range [0, max(candies)] such that we can still distribute

the candies to k children with each child receiving x candies. We consider a middle value mid within this range and check if it is possible to divide the piles in such a way that at least k children can receive mid candies each. If it is possible, then we know we can try to increase x and search in the upper half of the range; otherwise, we search in the lower half of the range.

The provided code implements this <u>binary search</u> approach to efficiently determine the maximum amount of candies that can be distributed to each child such that every child receives the same amount.

Solution Approach

can be distributed to each child and narrowing down that range to find an optimal solution.

Here's a step-by-step explanation of the implementation:

We initialize two pointers, left and right. left represents the lower bound (minimum number of candies we can give per

The solution provided is a binary search approach, which solves the problem by iterating over a possible range of candies that

child), set to 0, since it's possible that we cannot give any candies to the children if there are fewer candies than k. right represents the upper bound (maximum number of candies we can give to each child), which would be the largest pile in

candies, since no child can receive more than the size of the largest pile.
left, right = 0, max(candies)

We perform the binary search by checking the middle value between the left and right pointers. This middle value, mid,

For the current middle value mid, we calculate whether it is possible to achieve this distribution by summing up the number of

children we can satisfy if each were to be given mid candies. This is done by dividing each pile size by mid and summing those

posits a hypothetical maximum number of candies to be distributed per child.

mid = (left + right + 1) >> 1

values across all piles.

if cnt >= k:

return left

distribution.

Example Walkthrough

which is 9.

left = mid

cnt = sum(v // mid for v in candies)
 4. If cnt (the number of potential children receiving mid candies) is greater than or equal to k, then distributing mid candies to each child is possible, and we can potentially give more, so we adjust the left pointer to mid.

If cnt is less than k, then we cannot give out mid candies to each child, and we might need to reduce the number of candies

This search process continues until left and right converge, which happens when left == right. When the binary search

else: right = mid - 1

we give to each child. Therefore, we adjust the right pointer to mid - 1.

terminates, left will hold the maximum number of candies that we can distribute to each child.

We begin by initializing left = 0 and right = 19 (19 being the largest pile of candies).

To check the feasibility, we sum up how many children can receive 10 candies:

The total number of children who can receive candies is 0 + 0 + 1 + 1 = 2.

We repeat the binary search. Now, mid = (0 + 9 + 1) >> 1 is 5. We calculate:

The algorithm effectively uses <u>binary search</u> on a sorted range of possible candy distributions, utilizing the idea that if a certain amount x is doable, so is any amount less than x. We use division to check the feasibility of each mid point, counting the number of children that can be satisfied with mid candies and adjusting our search space accordingly until we find the maximum feasible

Let's take an example to illustrate the solution approach. Suppose we have an array of piles of candies given as candies = [4, 7,

We want to distribute these candies such that each of the 3 children gets the same number of candies, and we are tasked with

We perform binary search. Initially, mid = (0 + 19 + 1) >> 1 is 10. We check if we can distribute 10 candies to each child.

12, 19], and the number of children k = 3.

finding the maximum number of candies each child can get.

Pile 1 can be divided into 4 // 5 children, which is 0.

Pile 2 can be divided into 7 // 5 children, which is 1.

to each child, this is the most we can distribute evenly.

left, right = 0, max(candies)

if count >= k:

else:

return left

Java

left = mid

right = mid - 1

public int maximumCandies(int[] candies, long k) {

// that can be distributed to `k` children evenly.

// Calculate the middle point of the current search range.

// Perform a binary search to find the maximum number of candies

// Calculate the mid-point for the current search range

// Counter to record the total number of children we can distribute

// Increment the count by the number of children we can satisfy

// If we can give at least 'mid' candies to 'totalChildren' or more,

// Otherwise, reduce the upper bound of the search range

// After narrowing down the search range, 'minCandies' will hold the

// maximum number of candies that can be distributed to each child

// candies to with the current 'mid' number of candies per child

// with the current pile using 'mid' candies per child

int mid = (minCandies + maxCandies + 1) >> 1;

// Iterate through each pile of candies

childCount += candiesInPile / mid;

// adjust the lower bound of the search range

for (int candiesInPile : candies) {

if (childCount >= totalChildren) {

// that can be distributed to each child

while (minCandies < maxCandies) {</pre>

long long childCount = 0;

minCandies = mid;

maxCandies = mid - 1;

} else {

return minCandies;

TypeScript

Now, the total is 0 + 1 + 2 + 3 = 6.

Child 1 receives 5 candies from pile 2.

• Child 2 receives 5 candies from pile 3.

• Child 3 receives 5 candies from pile 4.

Python

class Solution:

Finally, the function returns the value of left as the answer.

Pile 1 can be divided into 4 // 10 children, which is 0.
 Pile 2 can be divided into 7 // 10 children, which is 0.
 Pile 3 can be divided into 12 // 10 children, which is 1.
 Pile 4 can be divided into 19 // 10 children, which is 1.

Since we can only satisfy 2 children, but we need to satisfy 3, 10 candies per child is too high. So, we set right = mid - 1,

Since the total number of children who can receive candies is now 6, and we only need to satisfy 3, we have found that giving

2 candies will remain in pile 3, and 14 candies will remain in pile 4, but since we can't combine them and we can only give one pile

Pile 3 can be divided into 12 // 5 children, which is 2.
 Pile 4 can be divided into 19 // 5 children, which is 3.

5 candies per child is possible. We could potentially give more, so we adjust left to mid, which is 5.

We continue this process, but now as left and right converge, both will be equal to 5, and the loop ends.

8. The binary search concludes with left = 5, which is the maximum number of candies we can distribute to each child.

Each child can receive 5 candies, which can be distributed as follows:

def maximumCandies(self, candies: List[int], k: int) -> int:

Initialize left to 0 (minimum possible result) and

right to the maximum number of candies in any pile

count = sum(candy // mid for candy in candies)

Binary search for the highest number of candies per child

Count how many children can receive 'mid' number of candies

If the number of children that can receive 'mid' candies is at least k,

Otherwise, we decrease the right pointer, as we need less candies per child

// Use `+ 1` to ensure the `mid` is biased towards the higher part of the range.

mid can be a potential answer, so we move left pointer up to mid

left is now the maximum number of candies per child that we can distribute

- Solution Implementation
 - while left < right:
 # Mid is the number of candies to distribute per child; add 1 and
 # shift right by 1 to get the upper middle for even numbers
 mid = (left + right + 1) // 2</pre>

// Initialize the search range for the maximum number of candies per child. int low = 0; int high = (int) 1e7; // Use a binary search to find the maximum number of candies

while (low < high) {</pre>

class Solution {

```
// The bitwise right shift operator `>> 1` effectively divides the sum of `low` and `high` by 2.
            int mid = (low + high + 1) >> 1;
            // Count the total number of children that can receive `mid` candies.
            long count = 0;
            for (int candy : candies) {
                count += candy / mid;
           // If the total number of children that can receive `mid` candies is at least `k`,
           // then we know that it's possible to give out at least `mid` candies to each child.
           // So we update `low` to `mid` to search in the higher half of the range next.
            if (count >= k) {
                low = mid;
           // If not, we need to search in the lower half of the range, so we adjust `high`.
           else {
                high = mid - 1;
       // `low` will represent the highest number of candies that can be distributed evenly to `k` children.
       return low;
C++
class Solution {
public:
    int maximumCandies(vector<int>& candies, long long totalChildren) {
       // Initialize the search range
        int minCandies = 0, maxCandies = 1e7;
```

```
// Function to calculate the maximum number of candies
// that can be distributed to each child
function maximumCandies(candies: number[], totalChildren: number): number {

left, right = 0, max(candies)

mid = (left + right + 1) // 2

maxCandies = mid - 1;

} else {

return minCandies;

while left < right:</pre>

if count >= k:

else:

return left

left = mid

right = mid - 1

class Solution:

```
Time Complexity
```

Time and Space Complexity

```
loop uses a binary search pattern which runs until left is less than right. In terms of the binary search, this takes

O(log(max(candies))) time, because we are repeatedly halving the search space that starts with the maximum value in candies.

Inside this loop, there is a sum operation which includes a list comprehension that iterates over all elements in the candies list.
```

resulting in O(n * log(max(candies))).

and does not grow with the size of the input.

once.
Since the list comprehension is done every time the while loop runs, the combined time complexity is the product of the two,

This operation has a time complexity of O(n) where n is the number of elements in candies, because it must visit each element

The time complexity of the given code is mainly determined by the while loop and the sum operation within that loop. The while

Space Complexity

The space complexity of the given code is 0(1). Despite the list comprehension inside the sum function, it does not create a new list due to the generator expression; instead, it calculates the sum on the fly. Thus, the only additional space used is for a few

variables (left, right, mid, cnt), which is constant and does not depend on the input size. Therefore, the space used is constant
