Problem Description

Greedy

Math

Array

The problem presents an array of positive integers and requires splitting this array into one or more disjoint subarrays. The split must be such that each element in the original array belongs to exactly one subarray. Additionally, for each subarray formed, the greatest common divisor (GCD) of its elements must be strictly greater than 1, meaning none of the subarrays should consist of elements that are only mutually prime. The objective is to find the minimum number of such subarrays that can be created following these rules.

Intuition

Medium

more elements are added to it. Starting from the first element, we can try to extend the subarray as much as possible until the GCD becomes 1. When the GCD is 1, it means that adding any more elements would not allow us to maintain the condition that the GCD is greater than 1. Therefore, we start a new subarray beginning at that point.

The approach incrementally builds subarrays and keeps track of the current GCD. Whenever the GCD becomes 1, the subarray is

The intuition behind the solution is leveraged from the fact that the GCD of a subarray can only decrease or stay the same when

finished, and a new one begins. The gcd function (presumably from math module or a similar implementation) calculates the GCD of two numbers and is repeatedly used to update the current GCD of each forming subarray. If at any point the GCD of the cumulative elements is 1, a split is made (indicated by incrementing the answer), and the GCD is reset to the value of the current element, thereby starting a new subarray. This process is repeated for all elements in the array, and the final answer denotes the minimum number of subarrays formed. The reason the starting value of ans is 1 in the solution is because at least one subarray is always possible, given that all the integers

are positive and the array cannot be empty. Solution Approach

The solution uses a greedy approach, where we try to extend a subarray as much as possible before needing to create a new

subarray so that the GCD of each subarray is greater than 1. Here's a step by step breakdown of how the solution is implemented:

2. Initialize a variable g to 0, which will store the running GCD of the current subarray.

If the GCD after adding x to the subarray becomes 1, then:

4. After iterating through all elements, return the value of ans.

3. Iterate over each number x in the array nums.

1. Initialize ans, the counter for minimum subarrays, to 1 because we can always form at least one subarray.

- Calculate the new GCD of the current subarray by taking the GCD of g (the GCD so far) and x (the current number). The
- GCD is updated using the statement g = gcd(g, x).
 - Increment ans by 1 as this signifies that a new subarray must start to fulfill the condition that each subarray must have a GCD greater than 1. Also, reset g to the value of x because a new subarray is starting with x as its first element.

If the GCD does not become 1, it implies that x can be added to the current subarray without violating the condition, and we

- continue to the next iteration.
- implemented if needed. This algorithm does a single pass over the input array (0(n)) time complexity, where n is the number of elements in the array) and only uses constant extra space (0(1) space complexity), making it efficient and suitable for large arrays as well.

The Python gcd function used in the code can be brought in by importing it from the math library (from math import gcd) or can be

By following this pattern, we can thus ensure that we always form subarrays with the maximum possible length without violating the GCD condition, which leads us to the minimum possible number of subarrays.

Following the steps outlined in the solution approach:

Example Walkthrough

1. Initialize ans to 1, as we can form at least one subarray.

Let's go through an example to illustrate the solution approach. Consider the array of positive integers [12, 6, 9, 3, 5, 7].

 For the first element 12, we calculate the GCD of g and 12. Since g is 0, the GCD is 12 (because the GCD of any number and 0 is the number itself). Now, g is updated to 12.

def minimumSplits(self, nums: List[int]) -> int:

Iterate over each number in the list

current_gcd = gcd(current_gcd, number)

// If the GCD is 1, a new split is required

// Return the total number of splits required

answer++; // Increase the number of splits

return splitsRequired; // Return the total splits required

currentGCD = number; // Reset the currentGCD to the current number

if (currentGCD == 1) {

Calculate the gcd of the current group and the current number

Initialize the variables:

for number in nums:

2. Initialize g to 0, to keep track of the GCD of the current subarray.

The third element is 9. The GCD of 6 and 9 is 3, so g is updated to 3.

Proceed with the array elements:

- Next is the number 3. The GCD of 3 and 3 remains 3, so we continue building this subarray. The fifth element is 5, and here the GCD of 3 and 5 is 1. Since the GCD has become 1, we need to start a new subarray. We
- increment ans to 2 and reset g to 5 (the current element).

Moving to the second element 6, the new GCD is the GCD of 12 and 6, which is 6. We update g to 6.

- The final element, 7, has a GCD of 1 with 5 (since 5 and 7 are prime with respect to each other), which would again imply the start of a new subarray. We increment ans to 3 and set g to 7.
- Therefore, the minimum number of subarrays where each subarray has a GCD greater than 1 is 3. These are [12, 6, 9, 3], [5], and [7].

subarray possible before needing to start a new one due to encountering a GCD of 1.

The example perfectly illustrates the efficiency and the greedy nature of the solution, where the algorithm tries to build the longest

'split_count' to count the minimum splits needed # 'current gcd' to keep track of the gcd of the current group split_count, current_gcd = 1, 0

31
Time and Space Complexity
```

The provided Python code defines a function minimumSplits that calculates the minimum number of non-empty groups to split the input list nums such that the greatest common divisor (GCD) of all numbers in the same group is not equal to 1.

Time Complexity:

The time complexity of the code is determined by the number of iterations in the for loop and the complexity of the gcd function calls within the loop.

• For each iteration, the GCD of the current running GCD g and the current element x is calculated using the gcd function. The time

complexity of the gcd function is generally O(log(min(a, b))) where a and b are the inputs to the gcd function. In the worst case, a and b could be the last two elements of nums.

• The for loop runs once for each element in nums. If n is the number of elements in nums, the loop iterates n times.

maximum element in nums due to the iterations where g is reduced to 1, resetting the GCD calculation. Overall, the worst-case time complexity of the minimumSplits function is O(n log m).

Since the GCD decreases or stays the same with each iteration, the time complexity is better than 0(n log m) with m being the

Space Complexity:

- The space complexity is determined by the additional space used by the function.
 - The variables ans and g use constant space.
- Since Python's gcd function has no additional space that depends on the input size (assuming it doesn't use a recursive stack) that depends on the size of the values), it can be considered to use constant space.
 - No additional data structures are used that grow with the size of the input.

Thus, the space complexity is 0(1) for constant extra space.
