2748. Number of Beautiful Pairs

Problem Description

The LeetCode problem provides an array nums, indexed from 0. We need to find all the "beautiful pairs" in this array. A pair of indices (i, j) is considered beautiful if the first digit of nums[i] and the last digit of nums[j] are coprime. Two numbers are coprime if their greatest common divisor (gcd) is 1, meaning they do not have any prime factors in common besides 1.

Leetcode Link

To solve the problem, we have to count each such pair where i < j.

To solve this problem efficiently, we recognize that there are only 10 possible digits (0 through 9), so it's possible to count

Intuition

provided keeps track of the count of leading digits encountered so far in a count array cnt, as we iterate through the array. For each number x in nums, we check if the last digit of x is coprime with each digit we've seen as a first digit, using the gcd function.

occurrences of leading and trailing digits without having to compare every possible pair (which would be inefficient). The solution

pairs. After checking against all first digits we've seen, we then record the first digit of x in our cnt count array, incrementing the count for that digit, which will be used for subsequent numbers in nums. This approach ensures that we are only iterating through the array once and are maintaining a constant-size array to track the

If they are coprime, we add the count recorded for that first digit to our answer ans, which accumulates the total number of beautiful

Solution Approach

The solution uses a count array cnt of size 10 (since we have 10 digits from 0 to 9) to keep a tally on the number of times a digit

appears as the first digit of a number in nums. Furthermore, it leverages the Greatest Common Divisor (gcd) to check for coprimality.

Here's a step-by-step breakdown of the algorithm: 1. Initialize a count array cnt with 10 zeros, corresponding to the digits from 0 to 9.

For every number x in nums:

counts of first digits, leading to a time-efficient solution.

3. Extract the **last digit** of x by calculating x % 10. 4. For every possible first digit y ranging from 0 to 9:

2. Initialize a variable ans to 0, which will hold the count of the beautiful pairs.

- Check if we have previously encountered y as a first digit (cnt [y] > 0). Calculate gcd(x % 10, y). If it is 1, x's last digit and y are coprime.
- If they are coprime, increment ans by the count of numbers (cnt[y]) that had y as their first digit.
- 5. Convert x to a string and take the first character, convert it back to an integer, and increment the respective count in cnt.
- numbers. Complexity is reduced from potentially O(n^2) to O(n) because we're only performing a constant amount of work for each of the n elements in nums.

Example Walkthrough Let's walk through a small example to illustrate the solution approach. Suppose our input array nums is [12, 35, 46, 57, 23].

By using this calculation method, only a single pass through the nums array is needed, and we avoid comparing every pair of

Now for each number in nums:

• For num 12:

 The last digit is 2 (12 % 10). • No other numbers have been processed yet, so we add 1 to cnt [1] because 1 is the first digit.

1. We initialize our count array cnt with 10 zeros: cnt = [0, 0, 0, 0, 0, 0, 0, 0, 0, 0].

 The cnt array becomes [0, 1, 0, 0, 0, 0, 0, 0, 0, 0]. For num 35:

2. We initialize our variable ans to 0.

 We check against all first digits we've seen so far, which is only 1. o gcd(5, 1) is 1, they are coprime, so we increment ans by the count of numbers with the first digit 1, which is 1.

For num 46:

ans becomes 1. We add 1 to cnt [3] for the first digit of 35.

The last digit is 5 (35 % 10).

The cnt array becomes [0, 1, 0, 1, 0, 0, 0, 0, 0, 0].

o gcd(6, 1) is 1, so they are coprime, increment ans by cnt[1] which is 1.

- The last digit is 6. We check against first digits 1 and 3 (from 12 and 35).
- gcd(6, 3) is 3, so 6 and 3 are not coprime, do nothing for cnt[3]. o ans becomes 2.

The cnt array becomes [0, 1, 0, 1, 1, 0, 0, 0, 0, 0].

We add 1 to cnt [4] for the first digit of 46.

We check against first digits 1, 3, and 4.

- For num 57:
 - o gcd(7, 1), gcd(7, 3), gcd(7, 4) are all 1, so 7 is coprime with 1, 3, and 4. o Increment ans by cnt[1] + cnt[3] + cnt[4] which is 1 + 1 + 1 = 3.

○ The last digit is 7.

 We add 1 to cnt [5] for the first digit of 57. The cnt array becomes [0, 1, 0, 1, 1, 1, 0, 0, 0, 0].

For num 23:

o ans becomes 5.

- The last digit is 3. We check against first digits 1, 3, 4, and 5.
- gcd(3, 1) is 1, so they are coprime, increment ans by cnt[1] which is 1. gcd(3, 3) is 3, so not coprime with itself, do nothing for cnt[3]. o gcd(3, 4) is 1, so they are coprime, increment ans by cnt[4] which is 1.

gcd(3, 5) is 1, so they are coprime, increment ans by cnt[5] which is 1.

 We add 1 to cnt[2] for the first digit of 23. The cnt array becomes [0, 1, 1, 1, 1, 1, 0, 0, 0, 0].

count = [0] * 10

answer = 0

return answer

 \circ ans becomes 5 + 1 + 1 + 1 = 8.

- After processing all the numbers, we have gone through the array once, and the total count of beautiful pairs ans is 8. Python Solution
 - from typing import List from math import gcd class Solution: def count_beautiful_pairs(self, nums: List[int]) -> int:

Return the total count of beautiful pairs

// Reduce the current number to its last digit.

beautifulPairs += countDigits[digit];

// Reduce the number to its least significant digit

// Increment the count of the least significant digit

while (number > 9) {

number /= 10;

++countDigits[number];

return beautifulPairs;

// Return the total count of beautiful pairs

// Increment the count of the last digit of the current number.

while (number > 9) {

number /= 10;

++countLastDigits[number];

Initialize count array with zeroes for each digit from 0 to 9

if count[digit] and gcd(number % 10, digit) == 1:

Initialize the answer to 0, which will hold the number of beautiful pairs

Iterate over each number in the input list for number in nums: 13 # Check each digit from 0 to 9 14 15 for digit in range(10):

Increment 'answer' by the count of that digit since it forms a beautiful pair

If there is a previously encountered number whose last digit has GCD=1 with current last digit of 'number'

```
19
                        answer += count[digit]
20
               # Increment the count of the first digit of 'number'
21
22
                count[int(str(number)[0])] += 1

Time and Space Complexity

if (b === 0) {

43

44

45

47

46 }

return a;

return gcd(b, a % b);

Time Complexity The time complexity of the given code is O(n) where n is the length of the input list nums. The analysis is as follows:

• Inside the loop, we execute a fixed number of iterations (10, for the range of y from 0 to 9), checking the greatest common divisor (gcd) of a pair of single digits. Since both the number of iterations and the gcd operation on single-digit numbers are constant-time operations, the loop inside does not depend on n and thus contributes a constant factor, 0(1), per each outer loop

We have a single loop that iterates over each element of nums, which contributes a factor of O(n) to the complexity.

- iteration. Updating the count array cnt also operates in constant time, 0(1), because it accesses a predetermined index determined by the first digit of x.
- Space Complexity

Hence, combining these, the time complexity is O(n) * O(1) = O(n).

// Recursive case: return the GCD of b and the remainder of a divided by b

The space complexity of the code is 0(1) which is a constant space overhead, regardless of the input size. This is explained as follows:

- The cnt array has a fixed length of 10, which does not depend on the size of the input list nums.
- As neither of these two grows with the size of the input nums, the space complexity of the algorithm is constant.

The ans variable is just a single integer counter.
