

Problem Description

In this problem, we are simulating the operation of a keypad being tested. The tester pressed keys in sequence, and we're given two pieces of information: the sequence of keys that were pressed and the times when each key was released.

The sequence of keys is represented by a string called keysPressed, where each character corresponds to a key that was pressed. The release times are given in an array releaseTimes, which includes the time when each key was released. Note that the array is sorted; the keys have been pressed in the order given by the string keysPressed, starting at time 0.

The duration of a keypress is defined as the time difference between the release of the current key and the release of the previous key. For the first key (index 0), its duration is simply its release time.

The aim is to find the key that had the longest keypress duration. If there are several keys with the same longest duration, we need to return the key with the highest lexicographical order (the one that appears last in the alphabet).

Intuition

To find the solution, we iterate through the keysPressed string and releaseTimes array to calculate the durations of all keypresses. To do this, we subtract the release time of the previous key from the release time of the current key.

maximum duration. As we loop through the keys:

We maintain two variables, mx for the maximum duration we have encountered so far and ans for the key that corresponds to this

- If we find a keypress duration longer than the current maximum duration (mx), we update both mx and ans with the new values. If we find a keypress duration equal to the maximum duration (mx), we compare the current key with the key in ans.
- lexicographically, and if the current key is lexicographically larger (i.e., it comes later in the alphabet), we update ans.

The logic above ensures that we will end with the key that has the longest duration, and if there is a tie, we will have the key with the highest lexicographical order.

The solution uses a straightforward iteration and comparison approach without the need for complex data structures or algorithms.

Solution Approach

The variables mx and ans hold the information of the maximum duration encountered and the corresponding key respectively. Here is a step-by-step breakdown:

1. Initialize mx with the release time of the first key, as there is no previous key to calculate the duration with, so the duration is

- releaseTimes[0]. 2. Initialize ans with the first key itself from the keysPressed string.
- 3. Loop through indices from 1 to len(keysPressed) 1 (since we have already used the 0th index for initialization). ∘ Calculate the duration d for the ith keypress as releaseTimes[i] - releaseTimes[i - 1].
 - Compare this duration with the current maximum duration mx.
 - If the current duration d is greater than mx, update both mx and ans with the current duration and key.
 - We compare keys by their ASCII values using ord(). If the ASCII value of the current key keysPressed[i] is greater than

If the current duration d is equal to mx, compare the keys lexicographically.

- that of ans (which means it is lexicographically larger), then update ans with the current key. 4. Continue this process until the loop finishes.
- 5. Return ans, which contains the key of the longest keypress duration or the lexicographically largest key if there are ties.
- By using this direct method, we ensure a time complexity of O(n), where n is the length of the keysPressed, which is optimal since we

have to examine each keypress to find the answer.

Let's walk through an example to illustrate the solution approach.

Example Walkthrough

Consider the input where keysPressed is "cbcd" and releaseTimes is [1, 2, 4, 7].

Following the step-by-step solution approach:

keypress is just its release time.

2. Initialize ans with the first key from the keysPressed string, which is "c".

1. Initialize mx with the release time of the first key, which is releaseTimes[0] = 1. There is no previous key, so the duration for this

- For index 1:

3. Now, we will loop through the indices from 1 to len(keysPressed) - 1, which in this case is from 1 to 3.

- Calculate the duration d as releaseTimes[1] releaseTimes[0], which is 2 1 = 1.
 - Compare d to mx. Here, d is equal to mx, which is 1. ■ Since d is equal to mx, we compare keysPressed[1] with ans lexicographically. Here, "b" is less than "c", so we don't
 - update ans.
- For index 2: ■ Calculate d as releaseTimes[2] - releaseTimes[1], which equals 4 - 2 = 2.
- Now d is greater than mx (2 > 1), so we update mx to 2 and ans to keysPressed[2] which is "c".
 - Calculate d as releaseTimes[3] releaseTimes[2], which equals 7 4 = 3.
- For index 3:
- Again, d is greater than mx (3 > 2), so we update mx to 3 and ans to keysPressed[3] which is "d". 4. After completing the loop, the maximum duration mx is 3 and the corresponding key ans is "d".

the key with the longest duration or the lexicographically largest one in case of ties.

def slowestKey(self, release_times: List[int], keys_pressed: str) -> str:

// Iterate through the release times starting from the second element

for (int i = 1; i < releaseTimes.length; ++i) {</pre>

// Calculate the duration the key was held down

int duration = releaseTimes[i] - releaseTimes[i - 1];

// Compare the current duration to the max duration

Initialize the slowest key with the first key pressed

Iterate over the keys pressed except the first one

- have returned the key with the highest lexicographical order.
- **Python Solution**

5. We return ans, which is "d". This is the key with the longest keypress duration. If there had been any ties, the solution would

There you have the walkthrough using the provided solution approach on a straightforward example. This shows how we can find

slowest_key = keys_pressed[0] # Initialize the maximum duration with the duration of the first key max_duration = release_times[0] 9

10

class Solution:

from typing import List

```

Time and Space Complexity

number of variables used in the function.

The provided Python code defines a function slowestkey that determines the character in keysPressed that has the longest duration between key presses. The code iterates through the keysPressed string and uses the releaseTimes list to find that character. Here's a breakdown of the time complexity and space complexity:

- Time Complexity: The time complexity of the function is O(n), where n is the length of the keysPressed string (and also the length of the releaseTimes list). This is because the code iterates through the keysPressed string exactly once.
- Space Complexity: The space complexity of the function is 0(1), which is constant space complexity. No additional space is used that scales with the input size. Only a fixed number of single-value variables are used (ans and mx), and their space usage

does not depend on the size of the input.

The time complexity is derived from the single loop running through the input lists, and the space complexity is based on the fixed
