

Problem Description

characters at certain indices across all the strings with the aim of making the resulting array of strings sorted in lexicographic (alphabetical) order. Lexicographic order means that the strings should appear as if they were sorted in a dictionary, i.e., strs [0] <= strs[1] <= strs[2] <= ... <= strs[n - 1].

In this problem, we are given an array strs containing n strings, where each string is of the same length. Our task involves deleting

We can select any number of indices to delete, and these deletions will occur on every string in the array. Our goal is to find the minimum number of indices that we need to delete to achieve the lexicographically sorted array. The problem asks us to return the

smallest possible size of the set of deletion indices. Intuition

To solve this problem, the intuition is to iteratively check each character column (index) across all strings and decide whether that

string lexicographically but has a greater character at the current index, then this column breaks the required order and must be deleted. Otherwise, if the current column does not break the order, we may keep it. However, simply looking at the current column in isolation is not sufficient. We must also remember if any prior columns have already established a strict lexicographic order between any two adjacent strings. If that's the case, these strings do not impact the decision

column should be deleted or kept to maintain the lexicographic order. If a column is found where a string appears before another

for the current column because they are already ordered properly due to previous columns. We keep track of these decisions using the cut boolean array, which marks pairs of strings that are already sorted and do not need to be considered again. The solution follows these steps: Iterate over each column (index) of the strings.

3. If the order is violated, increase the deletion count and skip to the next column.

- 4. If the order is maintained, mark any string pairs that are now sorted due to this column.
- Continue until all the indices have been processed.

2. Check if the character at the current column for each string maintains the lexicographic order with the next string.

- 6. Return the number of deletions that were necessary to sort the array lexicographically.
- Solution Approach
- The implementation of the solution uses a simple but effective approach to decide which columns (indices) need to be deleted to
- Here is how the approach is implemented:

Initiation: We begin by initializing the necessary variables:

len stores the length of the array A.

cut is a boolean array, initialized to false, that keeps track of which pairs of strings do not need further comparisons

ensure the strings are in lexicographic order.

because they are already in correct order according to prior columns.

wordLen stores the length of each string within the array.

res initialized to 0 will hold the count of indices required to be deleted.

- 2. Column-Wise Check: We inspect each column using the outer loop which iterates over j, the index for the character position within the strings.
 - after it (1 and 1+1). The main conditions checked in this loop are as follows: o If the cut[i] is false (meaning the strings at index i and i+1 have not been marked as already sorted) and the character at

the column j for string i is greater than the character at the same column for string i+1, it implies that the current column

3. Row-Wise Comparison: For each column, a nested loop goes through each string and compares it with the string that comes

violates the lexicographic order and thus we must "cut" this column by incrementing res by 1 and continue to the next column. If no lexicographic violation is detected, no increment to res will happen.

4. Mark Sorted Pairs: If a column does not lead to an increment of res, then for each string, excluding the last one, we check if the

character at the current column is less than the character in the same column of the next string. If it is, this means these two

strings are already sorted with respect to each other for the current column, hence we set cut[i] to true.

lexicographically, is returned as the final answer. 6. Algorithm Complexity: This approach would have a time complexity of O(N * W) where N is the number of strings and W is the width or length of each string. Space complexity is O(N) due to the additional array cut used to keep track of sorted pairs.

This algorithm uses a greedy approach, attempting at each step to make a local optimal decision (deleting a column if necessary),

which leads to a globally optimal solution—the minimum number of columns deleted to achieve the lexicographically sorted array of

5. Result: After inspecting all columns, the value res, which is the count of the indices that needed to be deleted to sort the strings

Example Walkthrough

Let's consider a small example to illustrate the solution approach. Suppose we have the following array of strings, where n=4.

Here our goal is to ensure this array is sorted lexicographically with the minimum number of column deletions. Step 1: We initialize our variables. len = 3, wordLen = 3, res = 0, and cut is an array of false values of size len - 1 which is 2 in this

• Comparing the first characters c, d, and g of each string, we see that they are already in the lexicographic order, so we don't

increment res. Additionally, we don't mark any pairs as sorted because c < d and d < g, indicating that the order cannot be

Step 2 & 3: We start checking each column, starting with the first column (index 0).

case, so cut = [false, false].

1 strs = ["cba", "daf", "ghi"]

strings.

affected by subsequent characters. Step 4: Move to the second column (index 1).

• Comparing the second characters b, a, h of each string, we notice the lexicographic order is violated (a should not come after b). Since cut [0] is false and 'a' < 'b', we need to delete this column to maintain the order. We increment res by 1 and we do not need to check further values in this column, so we continue to the next column.

Step 6: Having inspected all columns, we get res = 1 (since we had to delete the second column). This is the minimum number of

def min_deletion_size(self, strings):

if strings is None or len(strings) <= 1:</pre>

sorted_status = [False] * num_of_strings

for i in range(num_of_strings - 1);

Iterate over each column by index.

deletions += 1

// Return the total number of deletions.

return deletions;

for j in range(string_length):

deletions required to sort the strings lexicographically. Thus, our function would return 1 for this example.

Check if the input list is None or has only one string; if so, no deletion is needed.

If the current string is not sorted with the next, and the current character

break # Skip to the next column without updating the sorted status.

else: # This else belongs to the for, it is executed if the loop is not 'break'-ed.

Update sorted status if this column does not need to be deleted.

If the characters are in ascending order, mark as sorted.

Initialize a list to keep track of which strings are already sorted.

Attempt to update sorted status for this column.

Increment the deletion counter.

if strings[i][j] < strings[i + 1][j]:</pre>

for i in range(num_of_strings - 1):

Comparing the third characters a, f, i of each string, they are in correct lexicographic order, and no further action is needed.

6 # Initialize the number of strings and the length of the first string. num_of_strings = len(strings) 8 string_length = len(strings[0]) 9

deletions = 0

return 0

Step 5: Inspect the third column (index 2).

is greater than the next string's character, we need to delete this column. 20 if not sorted_status[i] and strings[i][j] > strings[i + 1][j]: 21 22 23 24

Time and Space Complexity
The time complexity of the given code can be analyzed based on the nested for-loops. The outer loop runs for j from 0 to wordLen,
```

// Check if input array is null or has only one string; if so, no deletion needed.

updating the cut array. Therefore, each character is visited once in the check and once in the update step for each inner loop, which leads to a total of O(wordLen * len) operations where wordLen is the length of the strings and len is the total number of strings.

The space complexity of the code is mostly dependent on the additional boolean array cut used to store the information on which strings do not need to be compared further. The cut array has a size equivalent to the number of strings len, so the space complexity is O(len).

and for each iteration of j, the inner loop runs for i from 0 to len - 1. There's also another nested loop with the same range for

Overall, the time complexity of the algorithm is 0(wordLen * len), and the space complexity is 0(len).
