74. Search a 2D Matrix

Problem Description

You are given a two-dimensional array, referred to as a 'matrix', where each row is sorted in ascending order, and the first element of each row is greater than the last element of the previous row. Your task is to check whether a given integer, 'target', exists within this matrix. To solve this problem efficiently, you must devise an algorithm that operates with a time complexity of O(log(m * n)), where m is the number of rows and n is the number of columns in the matrix. This time complexity hint suggests that we should consider a binary search approach, as it can perform searches in logarithmic time.

Intuition

Given the properties of the matrix, we can treat it as a sorted list. The idea here is that even though the matrix has two dimensions, the sorted nature of the rows and the rule that the first element of the current row is greater than the last element of the previous row means that a logical ordering exists as if all elements were in a single sorted list.

We can then apply a binary search on this 'virtual' sorted list. First, we initialize two pointers, left and right, which represent the start and end of the possible space where the target can be located. These are initially set to point to the first and last indices of this virtual list (0 and m * n - 1, respectively).

In each iteration of the binary search, we calculate the middle index, mid. We then convert mid back into two dimensions, x and y, using the divmod function, to compare the matrix element at this position against the target. If the element at [x] [y] is greater than or equal to the target, we bring the right pointer to mid, thereby discarding the second half of the search space. If the element is smaller, we increase the left pointer to mid + 1, discarding the first half of the search space. This process continues until the space

Finally, we check if the element at this narrowed down position is equal to the target. If so, we return true; otherwise, false. The binary search guarantees that we will find the target if it exists in the matrix within $0(\log(m * n))$ time complexity.

The solution approach implements a binary search algorithm, which is a classic method used to find an element within a sorted list in

Solution Approach

is narrowed down to a single element.

logarithmic time. However, in this context, we are using binary search on a two-dimensional matrix by treating it as if it were a linear array. Here's how it's done: • Variables Setup: We start by calculating the number of rows m and columns n of the matrix. We then set two pointers, left to 0

into a single list. • While Loop: The search process continues while left is less than right. This loop will terminate when left and right converge on the index where the target either is or would be if it were in the matrix.

and right to m * n - 1, which represent the range of possible indexes where our target might be if we were to flatten the matrix

• Mid Calculation and Conversion: Inside the loop, the mid-point index is calculated using the expression (left + right) >> 1, which is a bitwise operation equivalent to dividing the sum of left and right by two.

• Index Flattening: The mid index is then flattened into two dimensions, x and y, where x is the row number and y is the column

- number. This is achieved using the divmod function, where mid is divided by the number of columns n, x takes the quotient, and y takes the remainder of this division.
- o If matrix[x][y] is greater than or equal to the target, it means the target, if present, should be to the left, including the current mid. We then move the right pointer to mid.

• Search Space Halving: Depending on the value at matrix[x][y], we adjust our search space:

- o Conversely, if matrix[x][y] is less than the target, the target can only be on the right, excluding the current mid. We then set the left pointer to mid + 1. • Final Check: After the while loop, left should point to the index where the target would be if it's present. We take the left index
 - and convert it back into two-dimensional indices to access the matrix element. If matrix[left // n][left % n] is equal to the target, we return true, indicating the target is present in the matrix.
- This binary search algorithm effectively flattens the 2D search space into 1D, allowing us to utilize the time efficiency of binary search in a multidimensional context.

Example Walkthrough

value 9.

Matrix:

Let's illustrate the solution approach with a small example. Suppose we have the following matrix and we are looking for the target

```
Here's what the solution would look like step by step:
```

1.

Target:

2. While Loop Begins: Since left (0) is less than right (5), we continue our search.

3. Mid Calculation and Conversion: We calculate the middle index with the expression (left + right) >> 1, which gives us (0 + 5) >> 1 = 2. Now we need to convert this index back to two dimensions. Dividing 2 by the number of columns (3) gives us a

1. Variables Setup: We start by determining that the matrix has 2 rows (m) and 3 columns (n). We set our left pointer to 0 and our

right pointer to m * n - 1, which is 5 in this case (flattening the matrix to a single list would have indices ranging from 0 to 5).

4. Index Flattening: The element at the middle index, which is in the first row and third column of our matrix, is the number 5. We

quotient of 0 (row index x) and a remainder of 2 (column index y).

- compare this with our target 9. 5. **Search Space Halving**:
- Since 5 is less than 9, we can eliminate the first half of the search space and update our left index to mid + 1, which is 3. 6. While Loop Continues: With the updated left being 3 and right still 5, we continue our search.

7. Mid Calculation and Conversion: Recalculate mid with (left + right) >> 1, which gives us (3 + 5) >> 1 = 4. This mid index

corresponds to the second row and second column in our matrix. We divide 4 by the number of columns (3) to get x = 1 and y = 1

8. Index Flattening: The element at index 4 is 9 when looking at the matrix, which is exactly our target.

Initialize pointers for the binary search

left, right = 0, num_rows * num_columns - 1

If the middle element is greater or equal to the target, go left

If the middle element is less than the target, go right

// Map the middle index to a 2D position in the matrix.

// If the middle element is greater or equal to the target,

// narrow the search to the left half including mid.

// narrow the search to the right half excluding mid.

// If the middle element is less than the target,

// Compare the middle element with the target.

int x = mid / cols, y = mid % cols;

if (matrix[x][y] >= target) {

right = mid;

left = mid + 1;

} else {

Conduct a binary search in the matrix

if matrix[row][column] >= target:

By following these steps, this approach uses binary search to resolve the search problem within a two-dimensional matrix efficiently.

9. Final Check: Since matrix[x][y] is equal to the target 9, we have successfully found the target in our matrix! The loop

class Solution: def searchMatrix(self, matrix: List[List[int]], target: int) -> bool: # Get the number of rows and columns in the matrix num_rows, num_columns = len(matrix), len(matrix[0])

```
# Calculate the middle index between left and right
11
               mid = (left + right) >> 1 # Equivalent to floor division by 2 (mid = (left + right) // 2)
13
               # Convert the 1D representation mid back to 2D indices x and y
               row, column = divmod(mid, num_columns)
14
```

```
Typescript Solution
 1 // Function to perform binary search in a 2D matrix where each row and column is sorted.
2 // It returns true if the target number is found, otherwise returns false.
   function searchMatrix(matrix: number[][], target: number): boolean {
       // Get the number of rows in the matrix
       const numRows = matrix.length;
       // Get the number of columns in the matrix
       const numCols = matrix[0].length;
       // Initialize the left pointer to start the binary search
       let left = 0;
 9
       // Initialize the right pointer to the end of the logical 1D representation of the matrix
10
       let right = numRows * numCols;
11
12
13
       // Loop until the pointers meet, which means the target is not found if it exits the loop
       while (left < right) {</pre>
14
           // Calculate the mid point of the current search space
           const mid = Math.floor((left + right) / 2);
16
           // Compute the row index from the mid point
17
           const rowIndex = Math.floor(mid / numCols);
18
19
           // Compute the column index from the mid point
20
           const colIndex = mid % numCols;
           // If the element at mid position equals the target, return true for found
23
           if (matrix[rowIndex][colIndex] === target) {
24
                return true;
25
26
           // Otherwise, move the search space depending on the comparison with the target
28
           if (matrix[rowIndex][colIndex] < target) {</pre>
29
                left = mid + 1; // Move the left pointer to narrow the search space
30
            } else {
               right = mid; // Move the right pointer to narrow the search space
32
34
35
       // If we exit the loop, the target was not found in the matrix
36
       return false;
37 }
38
```

Time and Space Complexity

The time complexity of the searchMatrix function is $O(\log(m*n))$ where m is the number of rows and n is the number of columns in

elements. The search converges by halving the candidate range in each iteration. The space complexity of the searchMatrix function is 0(1). This is achieved as no additional storage that scales with the input size is

being used. All the operations are done in place with a few auxiliary variables that occupy constant space.

the matrix. This is because the function performs a binary search on a virtual flattened list representation of the matrix which has m*n
