Binary Search

Problem Description

<u>Array</u>

Hard

You also have k friends with whom you want to share the chocolate. You plan to make k cuts to the chocolate bar, resulting in k + 1 pieces, each composed of consecutive chunks.

In this problem, you are given an array sweetness, where each element represents the sweetness level of a chunk of chocolate.

Your goal is to be generous with your friends and, therefore, you will choose the least sweet piece for yourself. However, you want to optimize this so that this least sweet piece is as sweet as possible. The task is to find the maximum sweetness you can get for your piece after making the k cuts in the best possible way.

Intuition

The solution leverages a binary search algorithm to find the optimal maximum sweetness you can achieve for your chocolate

piece. The key insight is to realize that there is a range of possible sweetness levels for your piece – at the minimum, it could be the sweetness of the least sweet chunk, and at the maximum, it could be the total sweetness of the entire chocolate bar divided by k + 1. The binary search approach gradually narrows down this range by guessing a potential maximum sweetness (mid), then checking if it's possible to cut the bar into k + 1 pieces where each piece has at least this level of sweetness. The check

exceeds the guessed level before making a cut. If the function can make more than k such valid cuts, the guess is feasible, and it means you might be able to increase the sweetness level for your piece, so you search in the higher half. Otherwise, the guess is too high, and you search in the lower half. By repeatedly applying the binary search, you narrow down to the optimal 1 value, which represents the maximum sweetness you can achieve for your chocolate piece.

function is used to determine whether the current guess can be achieved by summing up the chunks' sweetness until it meets or

Solution Approach The solution uses binary search to efficiently find the optimal cut points within the chocolate bar to maximize the sweetness of the piece you will eat. Below is the step-by-step explanation of the implementation:

First, we establish the search boundaries for binary search. The 1 (left boundary) is initialized to 0, assuming we cannot have

the piece. It will return True if it is possible to cut the bar into more than k pieces where each piece has at least x

sweetness. The function does this by iterating over the sweetness values, accumulating them until they reach or exceed x,

a negative sweetness value, and r (right boundary) is initialized to the sum of all chunks' sweetness since this is the

maximum sweetness we could potentially achieve if we didn't have to share with anyone. We create a helper function check(x) with the parameter x representing the current guess for the maximum sweetness of

then making a virtual cut and proceeding with the rest of the chunks. Inside the while loop, which continues until 1 < r, we calculate the midpoint mid with (1 + r + 1) >> 1. The operation >>1 is equivalent to integer division by 2, so this finds the middle value between 1 and r. The +1 is important as it helps to avoid an infinite loop when 1 and r are close together.

The if condition inside the while loop uses the check(mid) function to decide which half of the current range to discard:

If check(mid) returns True, it means it's possible to cut the chocolate into pieces where each has at least mid

If check(mid) returns False, it means mid is too high of a value for the minimum piece sweetness that we can assure for ourselves after doing the cuts. Thus, we update r to mid - 1. The loop will exit when 1 equals r, which means we found the maximum sweetness that can still satisfy the conditions. The

solution returns 1, which is the optimal maximum sweetness we can achieve for our piece of chocolate.

Our goal is to find the maximum sweetness for the least sweet piece we can have after k cuts.

sweetness. Therefore, we should try to find a potentially higher minimum sweetness, and we update 1 to mid.

pieces are fair enough to be distributed to the k friends.

This algorithm ensures we arrive at the ideal maximum minimum sweetness while making sure that the rest of the chocolate

Let's go through an example to illustrate the solution approach. Suppose the sweetness array is [1, 2, 3, 4, 5, 6, 7, 8, 9],

maximum single piece's sweetness can't be more than 45/3=15. We create a helper function, check(x), which will go through the sweetness array, summing the values until it reaches or

We initialize 1=0 and r=45 because 45 is the total sweetness (sum of all chunks) and the k+1 pieces implies that the

First iteration: l=0, r=45, so mid=(0+45+1) >> 1 = 23.

Example Walkthrough

and you have k=2 friends.

• Check if it's possible to cut the bar so that each piece is at least 23 sweetness: No, because the highest sum we can get before the total sum exceeds 23 is 1+2+3+4+5+6=21, then 7+8+9=24, which only makes 1 cut. So, update r to mid - 1, which is 22.

be 7+8+9=24 (far exceeding 11, but it's the last piece, so it's okay). We managed more than k cuts here, so update 1 to mid, which is 11. Third iteration: l=11, r=22, so mid=(11+22+1) >> 1 = 17.

■ With 17, we can't reach the minimum sweetness before we've hit the end of the array (again, we get chunks like 1+2+3+4+5=15 and

■ Attempt with 14: We can have the pieces 1+2+3+4+5=15 and 6+7=13 (below 14, so we keep adding) then 8+9=17, we're just making 2

By the end of the last iteration, when 1 equals r, we have found the right cut-off (mid) where we can still have more than k

cuts. Since we succeeded in making k cuts before the sum fell short of 14, we can continue searching between 14 to 16.

■ Check if it's possible with 11: Yes, one piece can be 1+2+3+4=10 (which is just under 11), the next can be 5+6=11, and the last piece will

The process will continue, narrowing down the range until 1 equals r.

exceeds the current guess x, and then count a cut.

Second iteration: l=0, r=22, so mid=(0+22+1) >> 1 = 11.

Fourth iteration: l=11, r=16, so mid=(11+16+1) >> 1 = 14.

cuts with each piece being at least as sweet as our final value of 1.

def maximizeSweetness(self, sweetness: List[int], k: int) -> int:

def can divide(min_sweetness: int) -> bool:

if total >= min_sweetness:

total = 0

Initialize binary search bounds

left, right = 1, sum(sweetness)

return pieces > k

left = mid

right = mid - 1

pieces += 1

allows us to divide the chocolate into more than k+1 pieces

Perform binary search to find the maximum minimum sweetness

Return the maximum minimum sweetness value we found

// Function to maximize the minimum sweetness of the pieces divided

int maximizeSweetness(vector<int>& sweetness, int k) {

auto canAchieveSweetness = [&](int minSweetness) {

for (int pieceSweetness : sweetness) {

if (currentSum >= minSweetness) {

currentSum += pieceSweetness:

int left = 1; // minimum possible sweetness

int currentSum = 0, cuts = 0;

currentSum = 0:

if (canAchieveSweetness(mid)) {

// sweetness: vector of integers where each integer represents the sweetness of a piece

int right = accumulate(sweetness.begin(), sweetness.end(), 0); // maximum possible sweetness

// k: number of friends to share the sweetness with (pieces to divide into k+1)

// Helper lambda to check if a given minimum sweetness value is achievable

++cuts; // Increase count of number of cuts/pieces

// Binary search to find the maximum of the minimum sweetness that we can achieve

right = mid - 1; // Otherwise, search towards the lower end

// Define a helper function to check if it's possible to split the sweetness array

currentSweetness += value; // Add the sweetness value to the current sum

// Check if we can have more than k parts with the specified minimum sweetness

// into more than k parts where each part has a minimum total sweetness of x

// left will be the maximum of the minimum sweetness we can achieve

function maximizeSweetness(sweetness: number[], k: number): number {

let left = 0; // Initialize the lower bound of binary search

const canSplit = (minimumSweetness: number): boolean => {

if (currentSweetness >= minimumSweetness) {

partsCount++; // Increment the count of parts

int mid = left + (right - left + 1) / 2; // Midpoint and to avoid integer overflow

// If the current mid can achieve the minimum sweetness, search towards the higher end

let right = sweetness.reduce((a, b) => a + b); // Initialize the upper bound as the sum of sweetness

// If the current sum reaches the minimum sweetness threshold, we start a new part

currentSweetness = 0; // Reset the current sweetness for the next part

return cuts >= k + 1; // Check if we can make k+1 pieces

Calculate the middle point of the current search range

Helper function to check if the minimum sweetness value 'min_sweetness'

The +1 is because we need to divide the chocolate into k+1 pieces

'left' is the minimum possible sweetness, 'right' is the maximum possible sweetness

Otherwise, if we cannot, we look for a smaller minimum sweetness value

then 6+7+8+9=30), resulting in only 1 cut, so update r to mid - 1, which is 16.

Enter the binary search while-loop:

- The final value of 1 will be our answer. In this example, the maximum sweetness for the least sweet piece you can have would be 11 after iterating this process to the point where 1 and r converge.
- # Go through each piece of the chocolate for piece sweetness in sweetness: total += piece sweetness # If the total sweetness is at least 'min_sweetness', # we can form a new piece

mid = (left + right + 1) // 2# If we can divide the chocolate with 'mid' sweetness, # we trv to find a higher minimum sweetness value if can divide(mid):

else:

        while left < right:</pre>
           # Calculate the middle point of the current search range
           mid = (left + right + 1) // 2
           # If we can divide the chocolate with 'mid' sweetness,
           # we try to find a higher minimum sweetness value
            if can divide(mid):
                left = mid
```

The given Python code aims to maximize the sweetness of the piece a person can get after dividing the chocolate sweetness array into k + 1 pieces. It uses a binary search approach to find the solution.

Time and Space Complexity

right = mid - 1

Return the maximum minimum sweetness value we found

else:

return left

Time Complexity The binary search runs while 1 < r, which typically gives us a $0(\log n)$ complexity, where n is the range of values to be

Otherwise, if we cannot, we look for a smaller minimum sweetness value

searched—in this case, the total sum of the sweetness array (sum(sweetness)). Within each iteration of the binary search, the check function is called, which itself runs through the entire array once. Therefore,

this part has a time complexity of O(m), where m is the length of the sweetness array. Combining these two parts together, we get a total time complexity of 0(m * log n) for the entire algorithm, taking into account

the binary search and the linear scan in the **check** function for each mid value.

Space Complexity

The space complexity is 0(1). No additional space is allocated that grows with the size of the input, as the variables 1, r, mid, s, cnt, and x only use a constant amount of space.
