2475. Number of Unequal Triplets in Array

**Leetcode Link** 

**Problem Description** 

You are provided with an array of positive integers called nums. Each element of the array has a 0-based index. The task is to find out how many groups of three indices (i, j, k) exist such that the following conditions are met:

2. The values of nums at these indices are pairwise distinct. This means that nums[i], nums[j], and nums[k] should all be different

1. The indices are in strictly increasing order, i.e., i < j < k.

from each other. In other words, for a triplet (i, j, k) to be counted, it must consist of three unique numbers from the nums array, each coming from

a unique position in the array, where i, j, and k represent the positions (indices) of these numbers. The goal is to return the count of all such triplets.

Intuition

#### To solve this problem, we need to find a way to calculate the number of distinct triplets without having to manually check each possible combination, which would be inefficient especially for large arrays.

We can use the following approach:

2. Iterate through each unique number's frequency, calculating how many distinct triplets can be formed with it. The intuition stems from the fact that if we know how many times a particular number occurs, and how many numbers are before

and after it in the array (that haven't been used in a triplet yet), we can calculate all the valid triplets it can form.

1. Count the frequency of each number in the array using a data structure like a dictionary (Counter in Python).

Here are the steps taken in the solution code: Use Counter to get the frequency of each distinct number in nums.

• Initialize two counters, ans and a. ans will hold the final count of triplets, and a will keep track of the count of numbers processed so far.

Add this triplet count to the ans.

Let b represent the frequency of the current number.

Loop through the frequency count of each distinct number:

- ∘ Calculate c as the number of remaining elements that come after the current number, which is n a b (where n is the total length of nums). • The number of triplets we can form with the current number as the middle element is a \* b \* c. This product comes from
  - selecting one of the numbers before the current one (a choices), the current number itself (b choices), and one of the numbers after (c choices).
- Update a to include the current number as well by adding b to it. The final answer is contained in ans, so we return it.
- By using this method, we efficiently calculate the number of distinct triplets without the need to individually consider each possible combination of three numbers.
- Solution Approach

on: The total number of elements in nums.

the triplet) as c = n - a - b.

Let's consider an example nums array to illustrate the solution approach:

are used: Data Structures:

We use the Counter class from Python's collections module to efficiently count the frequency of each element in the nums

The solution approach is based on the concept of counting and combinatorics. To implement the solution, the following components

#### • A dictionary-like container maps unique elements to their respective frequencies. Variables:

array.

 ans: An accumulator to sum the number of valid triplets found. a: Keeps track of the number of elements processed so far (left side of the current element).

- Algorithm: 1. Count the frequency of each unique number using cnt = Counter(nums).
  - already processed. 3. Iterate over each count b in the values of cnt (since keys represent the unique numbers and values their respective counts):

cnt: A Counter object that holds the frequency of each unique element in nums.

• b: The frequency of the current element being considered as the middle element of a triplet.

• c: Represents the number of elements that are available to be picked after the current element.

ans. Update a to include the element just processed by adding b to it. 4. After the loop ends, ans holds the total number of valid triplets, which is returned as the final answer.

Each step of the algorithm is designed to avoid checking each triplet individually by leveraging the frequency counts and positions of

numbers to calculate the number of potential triplets directly. This leads to a more efficient implementation that can handle large

2. Initialize a variable ans to accumulate the total number of valid triplets and a variable a to keep track of the count of numbers

Calculate the number of available elements after the current element (which could potentially be the third element of

Calculate the number of triplets possible with the current number as the middle element as a \* b \* c and add this to

- arrays without incurring a performance penalty typical of brute-force solutions. Example Walkthrough
- From the problem statement, we want to count distinct triplets (i, j, k) such that nums[i], nums[j], and nums[k] are all unique. 1. First, we use Counter to get the frequency of each unique number in nums.

3. Initialize the variables ans for the total number of valid triplets and a for counting processed numbers.

1 from collections import Counter 2 cnt = Counter(nums) # cnt will be Counter({1: 2, 2: 2, 3: 1}) 2. We set n to the total number of elements in nums, which is 5.

4. Now, we iterate over each count b in the values of cnt. The dictionary cnt has elements along with their frequencies: {1: 2, 2:

#### 2 a = 0

yet).

First iteration (for number 1):

b for number 1 is 2.

Third iteration (for number 3):

ans remains 4.

from collections import Counter

2, 3: 1}.

1 ans = 0

1 nums = [1, 1, 2, 2, 3]

c = n - a - b which is 5 - 0 - 2 = 3. There are three elements that can come after the first 1 to form a triplet. ■ Triplet count for 1 is a \* b \* c = 0 \* 2 \* 3 = 0 (since a is 0, no triplets can be formed with 1 as the middle element

Update a = a + b to 2 (since we've now processed two occurrences of 1).

```
    Second iteration (for number 2):

    ■ b for number 2 is 2.
     c = n - a - b  which is 5 - 2 - 2 = 1 . There is one element that can come after 2 to form a triplet.
```

return 4.

class Solution:

10

11

13

17

18

25

26

27

Update ans by adding the triplet count, ans = ans + 4 to 4. Update a = a + b to 4 (as we've now processed two occurrences of 2).

without having to check each possible combination of three numbers.

def unequalTriplets(self, nums: List[int]) -> int:

number\_counts = Counter(nums)

answer = count\_first\_number = 0

# are all different

total\_numbers = len(nums)

# Count the frequency of each number in nums

# Iterating through the counts of each unique number

for count\_second\_number in number\_counts.values():

# Return the total number of unequal triplets

Map<Integer, Integer> frequencyMap = new HashMap<>();

// otherwise insert it with frequency 1

frequencyMap.merge(num, 1, Integer::sum);

// If the number is already in the map, increment its frequency,

// This function counts the number of unequal triplets within the input vector.

// Variable to store the result.

int accumulated = 0; // Accumulated counts of previous numbers.

// Increment the count for each value in the nums vector.

// Create a hash table to keep track of the count of each number in the vector.

int unequalTriplets(vector<int>& nums) {

for (int value : nums) {

int result = 0;

return result;

++numCounts[value];

unordered\_map<int, int> numCounts;

// Calculate the number of unequal triplets.

// Return the total number of unequal triplets.

for (auto& [value, count] : numCounts) {

• b for number 3 is 1. c = n - a - b which is 5 - 4 - 1 = 0. There are no elements left to form triplets with 3 as the middle element. ■ Triplet count for 3 is a \* b \* c = 4 \* 1 \* 0 = 0. No additional triplets can be formed.

5. After the iteration ends, and holds the total number of valid triplets. For this example, there are 4 valid triplets, and thus we

To conclude, using this example with nums = [1, 1, 2, 2, 3], the algorithm efficiently found the total number of 4 distinct triplets

■ Triplet count for 2 is a \* b \* c = 2 \* 2 \* 1 = 4. We can form 4 triplets with 2 as the middle element.

**Python Solution** 

# Initialize the answer and the count for the first number in the triplet

count\_third\_number = total\_numbers - count\_first\_number - count\_second\_number

# Calculate the number of triplets where the first, second, and third numbers

# Count of the third number in the triplet is total\_numbers

# minus the count\_first\_number and count\_second\_number

answer += count\_first\_number \* count\_second\_number \* count\_third\_number 20 # Increment count\_first\_number for the next iteration of the loop 23 count\_first\_number += count\_second\_number 24

```
class Solution {
    public int unequalTriplets(int[] nums) {
        // Create a map to store the frequency of each number in the array
```

30
Time and Space Complexity
```

## **Time Complexity**

# values of the Counter object cnt. The Counter object itself is created by iterating over the nums list once, which takes O(n) time where

n is the number of elements in nums. Inside the for loop, each operation is constant time, so the overall time complexity of the for loop is O(k), where k is the number of unique elements in nums. Since k can vary from 1 to n, in the worst case where all elements are unique, k is equal to n.

The time complexity of the code is primarily determined by the number of operations within the for loop which iterates over the

Therefore, the total time complexity is O(n) + O(k) = O(n) as the first iteration to create Counter and the second iteration over

**Space Complexity** 

The space complexity is affected by the storage used for the Counter object cnt which stores the frequency of each unique element

### in nums. In the worst case, if all elements of nums are unique, the Counter would take O(n) space where n is the number of elements in

unique values can be bounded by n.

Thus, the overall space complexity of the code is O(n).

nums.
