2844. Minimum Operations to Make a Special Number

The problem requires us to transform a given string num that represents a non-negative integer into a special number using a series of operations. A number is deemed special if it's divisible by 25. Every operation involves choosing and deleting any single digit from num, and this process can be done as many times as needed. If we end up deleting all digits, the string num becomes '0', which is a valid special number since 0 is divisible by 25. The ultimate goal is to find the minimum number of operations that make num a special number.

Leetcode Link

To find the minimum number of operations needed, we need to think about the properties of numbers divisible by 25. Any number

Intuition

divisible by 25 ends with '00', '25', '50', or '75'. Therefore, our task is to rearrange the digits of num by deleting some of them to get a number ending with these two digits. Let's focus on the two least significant digits in our operations because any digit(s) before them won't affect divisibility by 25 (e.g.,

125, 225, 1025 - all end with 25 and thus are special). For num to be special, it must end with any of the pairs mentioned. With this in

mind, we look for the occurrence of these pairs within num, and aim to remove as few digits as possible to form a special number. We can achieve this using a depth-first search (DFS) strategy. We explore each position i in the string num, where we either:

2. Take the current digit into consideration, add it to our forming number and check the number's remainder when divided by 25.

Using this approach, we can recursively calculate the minimum operations needed and employ memoization to avoid recalculations

1. Skip the current digit (which is equivalent to removing it) and recursively continue with the next digit.

(utilize previously solved sub-problems). Memoization is applied through the @cache decorator on the DFS function, which stores results of function calls with particular arguments for fast retrieval.

0), we need 0 more operations, otherwise, we haven't formed a special number and return a high operation count (n). The minimum of these recursive calls at each step gives the least operations needed.

The recursion continues until we've checked every digit in num (i == n), at which point, if we've formed a number divisible by 25 (k ==

Solution Approach The solution makes use of a recursive depth-first search (DFS) combined with memoization to optimize the computation. DFS is a powerful algorithmic technique for exploring all the options in a decision tree-like structure, one path at a time, until a goal state is

The core function dfs(i: int, k: int) -> int plays a crucial role in this approach:

reached.

• i tracks the current digit's index within num. • k is the current number formed by the selected digits from num, modulo 25. We use modulo 25 because we only care if the number formed is divisible by 25, not the actual number.

The base case for the recursion occurs when i equals the length of num (n). If k is 0 at this point, we've successfully formed a special

number, so no more operations are needed, and 0 is returned. Otherwise, we return n, which is a large number signifying an unsuccessful attempt to form a special number (since we cannot perform more operations than the number of digits).

Within dfs, we consider two options at each digit:

the result because skipping the digit is an operation. 2. Include the current digit: We call dfs(i + 1, (k * 10 + int(num[i])) % 25) to check if adding the current digit (int(num[i]))

brings us closer to making the number special. We perform modulo 25 on the result to update k.

Finally, the outer dfs call returns the minimum number of operations required to achieve the task.

1. Skip the current digit: We call dfs(i + 1, k) to continue to the next index while keeping the current value of k. We also add 1 to

Then, we use the min function to choose the option with the fewer operations. Memoization is applied using the @cache decorator from Python's standard library, which effectively caches the results of the dfs function calls with specific (i, k) pairs. The algorithm initiates with dfs(0, 0), meaning we start with the first digit and a k value of 0, indicating no number formed yet.

The data structure used here is implicit within the function call stack for the recursive approach, and the caching mechanism uses some form of hash table to store the results.

multiple times, thereby significantly reducing the time complexity compared to a plain recursive approach without memoization.

With this solution, we examine each possibility while ensuring we do not re-compute the same state (combination of i and k)

1. The goal is to minimize the operations to make "3527" a special number (divisible by 25). To do so, we need to find a way to end

2. We start with the recursive depth-first search (DFS) function dfs(i, k). Initially, we call dfs(0, 0) with i = 0 (which is the first

a. Skip the current digit: dfs(i + 1, k) and add 1 to the operations count.

Example Walkthrough

this number with '00', '25', '50', or '75'.

index of the string) and k = 0 (no number formed yet).

3. At each step of the recursion, we have two choices:

backtrack and try skipping some digits instead.

def minimum_operations(self, num: str) -> int:

def dfs(index: int, remainder: int) -> int:

Calculate the length of the input number string

return 0 if remainder == 0 else n

operations would look like this:

b. Include the current digit: dfs(i + 1, (k * 10 + int(num[i])) % 25).

number of operations is the one obtained from this branch of the decision tree, which is 1.

Let's consider an example where the input string num is "3527". Following the solution approach:

25) (including '3'). 5. Let's assume we first explore including the digit '3'. If we then include '5', the next steps are dfs(2, (3 * 10 + 5) % 25) ⇒

 $dfs(2, 35 \% 25) \Rightarrow dfs(2, 10)$. It looks like we won't end with '00', '25', '50', or '75' if we keep going this route. So we may

6. By applying the same decision logic to all possibilities, we find that to end with '25', we can skip '3' and keep '527'. The

4. For the first digit '3', the initial call is dfs(0, 0). Two recursive paths will be explored: dfs(1, 0) (skipping '3') and dfs(1, 3 %

a. dfs(1, 0) by skipping '3' (operations = 1). b. dfs(2, (0 * 10 + 5) % 25) by including '5' (operations still = 1) \Rightarrow this is dfs(2, 5). c. dfs(3, (5 * 10 + 2) % 25) by including '2' \Rightarrow this is dfs(3, 2).

d. dfs(4, (2 * 10 + 7) % 25) by including '7' \Rightarrow this is dfs(4, 0). At i = 4, which is the length of num, we check if k is 0, which

it is. Therefore, we've formed the number '527', which is divisible by 25, so no more operations are needed, and the minimum

7. If we had instead tried other combinations to end with '00', '50', or '75', we would have found that none of these paths gives a

Therefore, the answer for this particular num "3527" is 1. We perform one deletion operation (removing '3'), and then '527' is a special

- lower minimum operation count than ending with '25'. 8. The minimal number of operations is memorized for each state (i, k) to avoid redundant calculations.
- Python Solution from functools import lru_cache

Case 1: Exclude the current digit, increment the operations counter 17 exclude_current = dfs(index + 1, remainder) + 1 18 19 20 # Case 2: Include the current digit, no increment to operations counter

include_current = dfs(index + 1, (remainder * 10 + int(num[index])) % 25)

If current remainder is 0, it means we can form a number divisible by 25,

thus no more operations needed. Otherwise, we can't form such number hence return n

Define a Depth First Search with memoization using the lru_cache decorator

Base case: if we reached the end of the number string

Compute new remainder when the current digit is included

Start DFS from the first digit, with remainder initialized to 0

```
24
               # Choose the minimum operations between including or excluding the current digit
25
                best_option = min(exclude_current, include_current)
26
27
               return best_option
28
```

return dfs(0, 0)

number.

Time and Space Complexity

Time Complexity

return memo[currentIndex][remainder]; 26 27 **}**; 28 // Start the DFS from the first index with a remainder of 0

 There are n digits in the input string num, so there are n levels of recursion. At each level i, there are two choices: either take the current digit into consideration by calculating (k * 10 + int(num[i])) %

// Check if we already calculated the result for this subproblem

// Case 1: Skip the current digit, which costs us one operation

// compare with the result from skipping and choose the minimum

memo[currentIndex][remainder] = dfs(currentIndex + 1, remainder) + 1;

// Case 2: Take the current digit and update the remainder accordingly,

dfs(currentIndex + 1, (remainder * 10 + Number(num[currentIndex])) % 25)

if (memo[currentIndex][remainder] !== -1) {

memo[currentIndex][remainder] = Math.min(

// Return the computed minimum for this subproblem

memo[currentIndex][remainder],

return memo[currentIndex][remainder];

- 25 or skip it. • Memoization is used to avoid recalculating the states by storing results for each unique (i, k). The parameter i can take n different values (from 0 to n - 1) and k can take at most 25 different values (from 0 to 24) since we are only interested in the
- remainder when divided by 25. Due to memoization, each state is computed only once. Therefore, the time complexity is 0(n * 25), which simplifies to 0(n)

The given code defines a recursive function dfs with memoization to solve the problem. Let's analyze the time complexity:

because the 25 is a constant factor.

The space complexity is determined by the storage required for memoization and the depth of the recursion stack:

Space Complexity

- Due to memoization, we store results for each unique (i, k). Since i can take n different values and k can take 25 different
- values, the space required for memoization is 0(n * 25), which simplifies to 0(n). The recursion depth can go up to n levels, because we make a decision for each digit in the string num.
- Taking these into consideration, the overall space complexity of the algorithm is O(n) due to memoization and the recursion stack.
