

Problem Description

the odd positions (1st, 3rd, 5th, etc.) come before those at the even positions (2nd, 4th, 6th, etc.). It's important to maintain the original relative order of the nodes within the odd group and within the even group. For example, if the original linked list is $1 \rightarrow 2 \rightarrow 3$ \rightarrow 4 \rightarrow 5, after reordering it should look like 1 \rightarrow 3 \rightarrow 5 \rightarrow 2 \rightarrow 4. This reordering needs to be achieved with certain efficiency constraints: we can't use extra storage space, meaning we must rearrange the nodes in-place, and we must do it with a time complexity of O(n), where n is the number of nodes in the linked list.

Given the head of a singly linked list, we are tasked to reorder it in a specific way. We have to rearrange the nodes such that those at

Intuition

would require extra space, we can carefully rearrange the nodes by modifying their next pointers. The approach is to create two pointers, one that will traverse the odd nodes (a in the solution code) and another for the even nodes

To solve this problem efficiently, we exploit the in-place nature of linked list reordering. Instead of creating new lists or arrays which

by the updated a.next. This way, a is skipping over the even nodes to link together all the odd nodes, and b does the same among the even nodes. This also maintains the original relative order within each subgroup of nodes. After the loop, all odd-indexed nodes and even-indexed nodes are grouped separately, but we need to link the last node of the odd nodes to the first of the even nodes. To facilitate this, before starting the reordering process, we keep a separate pointer, c, at the

(b). The pointers essentially alternate, where a progresses to the node pointed to by b. next and b then moves to the node pointed to

first even node. When the reordering is complete (which is when b or b.next is None, indicating the end of the list), we simply link the last node of the odd-indexed group (pointed to by a) to the first of the even-indexed group (pointed to by c). At this point, our reordering is complete and we can return the head of the modified list as the final output. **Solution Approach**

without the need for additional data structures:

1. First, we initialize three pointers: • a, which starts at the head of the list and will be used to iterate over odd indexed nodes.

The implementation of the solution follows a specific pattern where the nodes are reordered in-place using only a few pointers,

o c, which keeps track of the head of the even indexed sublist (also starts at head.next).

(a. next skips an even node).

- 2. We enter a loop that continues until either b is None (meaning we've reached the end of the list) or b.next is None (meaning there
 - are no more odd nodes to process since odd nodes are followed by even nodes).

• b, which starts at the second node (head.next) and will be used to iterate over even indexed nodes.

- 3. Inside the loop: We link a.next to b.next, which is effectively connecting the current odd-indexed node to the next odd-indexed node
- We update a to be a.next so that it now points to the next odd-indexed node.
 - node. • We update b to be b.next to move to the next even-indexed node.

• We link b.next to a.next, since a has advanced one step, a.next is now an even-indexed node, and we need to skip an odd

- 4. After the loop, all odd nodes are now connected, and a points to the last odd node. We set a next to c, which links the end of the odd-indexed sublist to the head of the even-indexed sublist we tracked earlier.
- by even-indexed nodes. The above steps conform to the given constraints of 0(1) extra space complexity (since we're not using any additional data

structures) and O(n) time complexity (we go through the list at most twice, once for odd nodes and once for even nodes).

5. Finally, we return head, which now points to the reordered list where odd-indexed nodes are grouped at the beginning, followed

next pointers, which allows us to make changes in place.

The successful execution of this pattern depends heavily on the understanding of linked list structure and careful manipulation of

Let's walk through the provided solution approach with a small example to illustrate the method. Suppose we have a linked list: 1 -> 2 -> 3 -> 4

a starts at 1 (head of the list).

1. We set up our three pointers:

Example Walkthrough

 b starts at 2 (second node, head.next). c also starts at 2 (head of the even sublist).

2. Enter the loop. Currently, b is not None nor is b.next None, so we proceed.

3. First iteration:

1 -> 3 -> 4 -> 2 -> NULL

 Since a moved, we now update b.next (2's next) to a.next which does not change anything since a.next is still 4. Move b to b.next (now b is at 4).

Link a.next (1's next) to b.next (3). Now the list looks like: 1 -> 3 -> 4

The list now effectively looks like this, with the pointers at their respective positions (a = 3, b = 4, c = 2):

Move a to a.next (now a is at 3).

4. Continue the loop. Now, b. next is None, we exit the loop.

Each step in this approach closely adheres to the specified pattern, ensuring the final output is achieved with an O(n) time

5. Connect the last odd node (a, now at 3) to the head of the even sublist (c, which is still at 2): 3 -> 2. The list now becomes:

6. Finally, return the head of the reordered list, which is still at 1. The fully reordered list, illustrating odd-positioned nodes followed

1 -> 3 -> 2 -> 4 -> NULL

Definition for singly-linked list.

odd_ptr = head

by even-positioned ones, is now:

complexity and without using any extra space. The list provided has been reordered in place effectively.

Function to rearrange nodes of a given linked list such that all

def oddEvenList(self, head: Optional[ListNode]) -> Optional[ListNode]:

Initialize two pointers, one for odd indexed nodes (odd_ptr)

the start of even indexed nodes (even_head).

// Initialize pointers for manipulation.

// Iterate over the list to rewire nodes.

// Link the next odd node.

// Link the next even node.

odd.next = even.next;

even.next = odd.next;

even = even.next;

odd = odd.next;

while (even != null && even.next != null) {

ListNode odd = head;

ListNode even = head.next;

ListNode evenHead = even;

// 'odd' points to the last node in the odd-indexed list.

// Move the 'odd' pointer to the next odd node.

// Move the 'even' pointer to the next even node.

// 'even' points to the last node in the even—indexed list.

// 'evenHead' points to the first node of the even-indexed list.

and one for even indexed nodes (even_ptr), and also keep track of

the odd indexed nodes appear before all the even indexed nodes.

Python Solution

1 -> 3 -> 2 -> 4

def __init__(self, val=0, next=None): self.val = val self.next = next

If the list is empty, nothing needs to be done. 11 if head is None: 12 13 return None 14

39
Time and Space Complexity
```

The given Python code reorders a linked list so that all the odd nodes are listed before the even nodes, maintaining their relative

order. To analyze the time complexity and space complexity of the function oddEvenList, let's go through it step by step:

• The while loop continues until it has traversed all the nodes of the linked list because it stops only when b is None (meaning the end of the list) or b.next is None (meaning the last node is reached).

Time Complexity:

- Inside the loop, operations have a constant time complexity (0(1)), which includes assigning next pointers for a and b. • Since each node is visited once during the traversal, the total time complexity is based on the number of nodes in the linked list
- (n). Therefore, the time complexity is O(n) where n is the number of nodes in the linked list.
- The algorithm only uses a constant amount of extra space for pointers a, b, and c irrespective of the size of the input linked list.

Space Complexity:

 No additional data structures are used that grow with the input size. Therefore, the space complexity is 0(1) constant space.
