

Problem Description

horizontal axis represents the points 0 to n and the vertical axis represents the 3 lanes. A frog starts on the second lane at point 0 and aims to get to any lane at point n. Along the way, the frog might encounter obstacles.

In this problem, we have a road that has exactly three lanes and extends from point 0 to point n. Picture the road as a grid where the

The obstacles array contains n+1 elements where each element indicates if there's an obstacle in a specific lane at a specific point. If obstacles[i] is 0, there are no obstacles at point i; otherwise, the value of obstacles[i] signifies which lane has an obstacle at point i.

can jump to another lane at the same point without moving forward, but only if there's no obstacle in the destination lane. Note that such sideways jumps are not free; our goal is to help the frog reach point n with the minimum number of these side jumps. Here are the key points:

The frog can only move forward from a point i to point i+1 if there isn't any obstacle on the lane at point i+1. In addition, the frog

 Obstacles are represented in an array, with obstacles[i] indicating an obstacle on lane obstacles[i] at point i (obstacles[i] ranges from 0 to 3, where 0 means no obstacle).

The frog starts in the second lane at point 0.

- The frog can move forward on the same lane or jump to a different lane at the same point (sideways). There are never any obstacles at the start or end points (0 and n). • We need to calculate the minimum number of side jumps needed for the frog to reach any lane at point n.
- Intuition
- To solve this problem, we need to track the frog's potential positions and the number of jumps needed to reach those positions. We

jumps needed to reach that lane at the current point.

Here's the approach step by step: 1. Initialize an array f with three elements, one for each lane, with the initial values set to represent the number of side jumps needed to start in the middle lane (which would be 0 for lane 2 and 1 for lanes 1 and 3 since the frog starts in lane 2 and would

can do this by maintaining an array where each element corresponds to a lane and holds the count of the minimum number of side

2. Begin iterating through each point on the road, which are represented by the elements of the obstacles array excluding the first

need one jump to reach the others).

any lane at the destination point n.

- element (since there's no obstacle at point 0). 3. For each point, check if there's an obstacle in a lane. If there is, mark the corresponding element in f as infinity (inf) to represent that the lane is blocked and therefore cannot be the minimum. 4. Find the minimum value in f and increment it by 1. This accounts for the possibility of a side jump to avoid the current obstacle.
- 5. Update the values in f for lanes without obstacles at the current point. Their values are set to either their current value or the incremented minimum from the previous step, whichever is lower. This represents the minimum side jumps to reach that lane up to the current point, either by being there already or by making a jump.

6. After processing all points, the minimum value in the modified f array will represent the minimum number of side jumps to reach

- Following this strategy will dynamically update the minimum jumps needed for each lane at each point, taking into consideration the possibility of avoiding obstacles by side jumping, leading us to the solution of the minimum side jumps throughout the entire road.
- **Solution Approach**

The Python solution provided defines a class Solution with a method minSideJumps, which takes the obstacles array as an argument. This method implements dynamic programming to compute the minimum number of side jumps the frog needs to reach the end of the road.

1. Dynamic Array Initialization: A list f with three elements is initialized to [1, 0, 1]. These elements correspond to the number of

side jumps needed to reach lanes 1, 2, and 3 respectively from the starting position (lane 2 at point 0). The frog is starting in the

middle lane, so it requires no side jumps (f[1] = 0), but would require a side jump to get from the middle lane to either of the

additional jump.

outer ones initially (f[0] and f[2] initialized to 1).

and the present obstacle configuration at each point.

There are no obstacles at point 0 and point 5.

At point 4, the obstacle is in lane 3.

having to jump away from an obstacle in the current position.

the obstacles are represented by the following array: [0,1,0,2,3,0]. This means:

2. Iterating Over Obstacles: The method then iterates through the obstacles array, starting at index 1 until the end (obstacles[1:]). This skips the starting point where we're guaranteed to have no obstacles. 3. Updating Array per Obstacle: For each point i, the list f is updated as follows:

If there's an obstacle in lane j, set f[j] to infinity (inf) to indicate that this lane is no longer an option without making an

Calculate the minimum number of side jumps needed up to this point, which is min(f) + 1. The + 1 accounts for potentially

number of side jumps to be at each lane at the current point: • If there's no obstacle in lane j, set f[j] to the minimum of its current value and the new calculated value x. 5. Return Minimum Jumps to Reach End: After all obstacles have been processed, the method returns the minimum value in f,

This approach uses the dynamic programming pattern, where the f list serves as a memoization storage to keep track of the optimal

number of side jumps up to each point. The solution leverages the concept of updating potential future states based on current state

which represents the minimum number of side jumps the frog needs to reach the end, across all three lanes.

4. Updating Array for Movement Options: The list f is then updated again for each lane, ensuring that it represents the minimum

- The overall algorithm complexity is O(n), where n is the number of points (n+1 points for a road of length n), because it processes
- each point exactly once, doing a constant amount of work for each. **Example Walkthrough**

Let's consider a small example to illustrate the solution approach. Assume we have the road from point 0 to point n, with n = 5, and

 At point 1, the obstacle is in lane 1. There's no obstacle at point 2. At point 3, the obstacle is in lane 2.

3 respectively from lane 2 at point 0.

point.

The frog starts in lane 2 at point 0 and wants to end up at any lane at point 5 with the least side jumps possible. 1. Dynamic Array Initialization: We start with the list f = [1, 0, 1], which is the number of jumps needed to get to lanes 1, 2, and

2. Iterating Over Obstacles: We start iterating over the obstacles, skipping the first one because there's no obstacle at the starting

4. Minimum Jump Calculation: Look for the minimum number of side jumps which is min(inf, 0, 1) and the result is 0. Add 1 for

3. First Obstacle: We encounter the first obstacle in lane 1 at point 1. We set f[0] to infinity. Now f = [inf, 0, 1].

potential side jump so, min_jump = 0 + 1.

6. No Obstacle at Point 2: No updates since obstacles [2] is 0.

minimum value in f for the lanes without infinity.

def minSideJumps(self, obstacles: List[int]) -> int:

for obstacle_position in obstacles[1:]:

if obstacle_position == lane + 1:

min_jumps_plus_one = min(jumps_count) + 1

jumps_count[lane] = float('inf')

 $jumps_count = [1, 0, 1]$

for lane in range(3):

for lane in range(3):

Initialize the number of side jumps for each lane at the start.

Lane 2 has 0 jumps (since the frog starts here), others have 1 jump.

Iterate through the obstacle positions, starting from the second position.

Update the jump count to infinity for the lane with the obstacle.

Find the minimum jumps needed plus one for the potential jump.

// Method to find the minimum number of side jumps to reach the end of the array.

// Update the number of jumps to INF if there is an obstacle in the lane.

// If there is an obstacle in the current lane, set jumps for that lane to infinity.

for (int position = 1; position < obstacles.length; ++position) {</pre>

for (int position = 1; position < obstacles.size(); ++position) {</pre>

int minJumps = std::min({lanes[0], lanes[1], lanes[2]}) + 1;

lanes[lane] = std::min(lanes[lane], minJumps);

// Update the jumps needed for now obstacle-free lanes

// If there's an obstacle in the lane, set jump count to infinity

// Find the minimum number of side jumps required to reach this position

// If there's no obstacle in the lane, take the min of the current

// and the just computed min jumps needed to reach this position

// Update lane status based on obstacles

if (obstacles[position] == lane + 1) {

if (obstacles[position] != lane + 1) {

// Return the minimum number of jumps among the three lanes

for (int lane = 0; lane < 3; ++lane) {</pre>

for (int lane = 0; lane < 3; ++lane) {</pre>

return std::min({lanes[0], lanes[1], lanes[2]});

lanes[lane] = INF;

break;

for (int lane = 0; lane < 3; ++lane) {</pre>

jumps[lane] = INF;

if (obstacles[position] == lane + 1) {

Update the jump counts for lanes that do not have the current obstacle.

break # No need to check other lanes after finding the obstacle.

5. Update For Movement Options: Since lanes 2 and 3 are clear at point 1, set f[1] and f[2] to the minimum of their current value and min_jump, thus remaining as f = [inf, 0, 1].

7. Second Obstacle: We encounter an obstacle in lane 2 at point 3. We set f[1] to infinity. Now f = [inf, inf, 1].

8. New Minimum Jump Calculation: Only lane 3 is available with the current minimum of 1, so $min_jump = 1 + 1 = 2$. 9. Update For Movement Options: Only lane 3 is available; no change occurs as f = [inf, inf, 1].

11. Final Minimum Jump Calculation: This doesn't affect the minimum jump count since this happens at the last point, and lane 2

doesn't need additional jumps to reach the end. 12. Return Minimum Jumps to Reach End: The minimum number of jumps needed for the frog to finish is still 1, which is the

was 1. This helps us to visualize how the solution adapts to the dynamic array f as it processes the obstacles on the road.

10. Third Obstacle: We encounter an obstacle in lane 3 at point 4. We set f[2] to infinity. Now f = [inf, inf, inf].

Python Solution

Upon reaching point 5, any lane will do, and the minimum number of side jumps the frog needed to make to get there in this example

20 if obstacle_position != lane + 1: 21 jumps_count[lane] = min(jumps_count[lane], min_jumps_plus_one) 22 23 # Return the minimum jumps count from the updated jump counts. 24 return min(jumps_count) 25

public int minSideJumps(int[] obstacles) { final int INF = Integer.MAX_VALUE; // Use a large number to represent an 'infinite' number of jumps. int[] jumps = {1, 0, 1}; // Array to store the minimum jumps needed to reach each lane at the current point. // Iterate over the obstacle array, skipping the first element as the starting point is fixed.

conditions. It does not use nesting of loops; hence other than the linear pass through the obstacles, there aren't additional multiplicative factors contributing to the time complexity.

Space Complexity:

Time Complexity:

Time and Space Complexity

The space complexity of the provided code is 0(1). This is because the space used by the algorithm does not scale with the input size n. The f array is of a fixed size of 3, representing the number of lanes. There are no other data structures used that grow with the input size. Thus, regardless of the size of the obstacles list, the amount of space used by the algorithm remains constant.

The time complexity of the provided code is O(n) where n is the number of elements in the obstacles list. The algorithm iterates

through each of the n obstacles once. Within this loop, it performs constant-time operations - updating the f array and checking
