## 2138. Divide a String Into Groups of Size k

**Problem Description** 

This problem is about partitioning a string s into several groups of characters. Each group must contain exactly k characters. The partitioning follows a set procedure:

Leetcode Link

of the string. If the remaining characters at the end of the string are fewer than k, we fill the last group with a fill character fill to make sure it

We start from the beginning of the string and create groups by sequentially taking k characters for each until we reach the end

also has exactly k characters. The constraint is that after removing any fill characters added to the last group and then concatenating all groups, we should get

the original string s.

The goal is to return an array of strings, where each element is one of the groups created by this procedure.

The solution relies on a straightforward approach:

Intuition

 Iteratively process the string in increments of k characters. For every k characters, we take a substring from the original string s and add it to the result list.

- We use a Python list comprehension to perform this operation concisely. The list comprehension iterates over the range of indices starting from 0 up to the length of the string s, skipping k indices at a time.
- For each iteration, we take a slice of the string s from the current index i up to i + k. If i + k exceeds the length of the string s, Python's slice operation will just return the substring up to the end of the string, which would be less than k characters.
- To ensure that each substring in the result list has exactly k characters, we use the .ljust() string method. This method pads the string on the right with the fill character until the string reaches a specified length (k in our case). If the substring already has k characters, .ljust() leaves it unchanged.
- This solution is efficient and only goes through the string once. It also takes care of the edge case where the last group is shorter than k characters without needing additional conditional checks. By leveraging Python's string slicing and the light () method, we achieve an elegant and efficient solution that directly constructs
- the desired array of group strings. Solution Approach

solution uses Python list comprehension, string slicing, and the str.ljust method. Let's walk through the key parts of the

In the given problem, we have a simple yet efficient solution that efficiently partitions the string into the required groups. The

### implementation:

• List Comprehension: This is a concise way to create lists in Python. It allows for the construction of a list by iterating over some sequence and applying an expression to each item in the sequence. In our case, we generate a list that contains each group of the partitioned string s.

String Slicing: A vital feature of Python that allows us to extract a specific portion of a string using the syntax

string[start:end], where start is the index of the first character inclusive and end is the index of the last character exclusive. If end extends beyond the length of the string, Python simply returns the substring up to the end without raising an error. • str.ljust(k, fill) Method: This string method left-justifies the string, using fill (a single character) as the fill character, until

the whole string is of length k. If the string is already k characters or longer, no filling occurs. This method is perfect for ensuring

that each group is exactly k characters long, even the last group if it's originally shorter than k characters. The implementation is straightforward:

1. We iterate over the indices of the string s with the range() function, starting from 0 and ending at len(s), taking steps of k at a

3. We apply the ljust() method to each substring with the specified fill character to ensure it is k characters long. After iterating over all possible starting indices that are k characters apart, we collect all the modified substrings into a list. This list

2. For each index i, we slice the string s from i to i+k. This gives us a substring of s which is at most k characters long.

time. This ensures that each iteration corresponds to a group of k characters.

represents the groups after the partitioning process and is the final output of the function.

The code for creating each group looks like this: 1 [s[i:i+k].ljust(k, fill) for i in range(0, len(s), k)]

achieve the desired result with minimal code.

character fill = "x" to use if necessary.

fill character if needed.

Example Walkthrough Let's assume our input string s is "abcdefghi" and we are to partition this string into groups of k = 3 characters. We also have a fill

As a result, we get a list of strings, each representing a group of s that is exactly k character long, where the last group is filled with

This approach is both simple to understand and effective at solving the problem, utilizing core Python string manipulation features to

groups would be "abc," "def," and "ghi." Since "ghi" has exactly 3 characters, there is no need to use the fill character in this example.

3. Move to the next k characters, increment i by k to i = 3, and take the substring s[3:6], which gives us "def".

According to the problem description, we would start at the beginning of the string and take groups of k characters in sequence. Our

We now have the strings "abc," "def," and "ghi". All of these are of length k, so the ljust method is not necessary in this case.

We can illustrate the solution approach with the following steps:

1. Start at the beginning of the string, with i = 0.

However, if we had a different string, let's say s equals "abcdefg", with the same value for k, we'd have an additional step for the last group:

fill character "x" to get "gxx".

"abc"

"def"

"gxx"

2 class Solution:

result = []

30 }

Following the previous steps, we would get "abc" and "def".

The list comprehension puts this all together elegantly, completing the task in a single line of code.

# Extract the chunk from the string starting at index `i` up to `i + k`.

# If the length of the chunk is less than `k`, fill it with the fill character.

2. Take the substring from i to i + k, which translates to s[0:3]. This gives us "abc".

4. Continue the process by setting i to 6 and taking the substring s [6:9], yielding "ghi".

has k characters. If the last group is originally shorter than k characters, it gets padded with fill until it's k characters long. So, the partitioned groups for "abcdefg" will be:

Thus, the use of s[i : i + k].ljust(k, fill) in our list comprehension is to handle cases like this, ensuring the last group always

2. The next i is 6. The substring s [6:9] would result in "g". Since this group is less than k characters, we need to pad it with the

Python Solution # Solution class containing the method to divide and fill a string.

# The `ljust` method is used to fill the chunk with the given character until it reaches the desired length.

# This method takes in a string 's', a chunk size 'k', and a fill character 'fill'. # It divides the string `s` into chunks of size `k` and if the last chunk # is smaller than `k`, it fills it with the `fill` character until it is of size `k`. # The method returns a list of these chunks.

for i in range(0, len(s), k):

chunk = s[i : i + k]

# Return the list of chunks.

filled\_chunk = chunk.ljust(k, fill)

result.append(filled\_chunk)

def divideString(self, s: str, k: int, fill: str) -> list[str]:

# Initialize an empty list to store the chunks of the string.

# Loop through the string in steps of `k` to get each chunk.

# Append the filled chunk to the `result` list.

partitions[i] = input.substring(start, end);

// Return the final array of partitions.

return partitions;

```
25
            return result

Java Solution
   class Solution {
       public String[] divideString(String input, int partitionSize, char fillCharacter) {
           // Determine the length of the input string.
           int inputLength = input.length();
           // Calculate the required number of partitions.
           int totalPartitions = (inputLength + partitionSize - 1) / partitionSize;
           // Initialize the answer array with the calculated size.
10
            String[] partitions = new String[totalPartitions];
11
12
           // If the input string is not a multiple of partition size, append fill characters to make it so.
13
           if (inputLength % partitionSize != 0) {
                input += String.valueOf(fillCharacter).repeat(partitionSize - inputLength % partitionSize);
14
15
16
17
           // Loop through each partition, filling the partitions array with substrings of the correct size.
18
           for (int i = 0; i < partitions.length; ++i) {</pre>
               // Calculate the start and end indices for the substring.
19
20
               int start = i * partitionSize;
21
                int end = (i + 1) * partitionSize;
```

// Extract the substring for the current partition and assign it to the partitions array.

#### 2 public: // Function to divide a string into substrings of equal length k. // If the length of string s is not a multiple of k, fill the last substring with the 'fill' char.

C++ Solution

1 class Solution {

```
vector<string> divideString(string s, int k, char fill) {
            int stringLength = s.size();
           // If string length is not a multiple of k, append 'fill' characters
           if (stringLength % k) {
 8
               for (int i = 0; i < k - stringLength % k; ++i) {
 9
                   s.push_back(fill);
10
11
12
13
           vector<string> substrings;
14
           // Divide the string into substrings of length k
15
            for (int i = 0; i < s.size() / k; ++i) {
               substrings.push_back(s.substr(i * k, k));
16
17
           return substrings; // Return the vector of substrings
18
19
20 };
21
Typescript Solution
   // Declare an array to store the resulting substrings
   const substrings: string[] = [];
   // Function to divide a string into substrings of equal length `k`
   // If the length of string `s` is not a multiple of `k`, fill the last substring with the `fill` character
    function divideString(s: string, k: number, fill: string): string[] {
        let stringLength: number = s.length;
 8
       // If string length is not a multiple of `k`, append `fill` characters
 9
       while (stringLength % k !== 0) {
10
```

# Time and Space Complexity

s += fill;

stringLength++;

// Divide the string into substrings of length `k`

substrings.push(s.substring(i, i + k));

for (let i = 0; i < s.length; i += k) {

#### 20 // Return the array of substrings 21 return substrings; 22 } 23

**Time Complexity:** 

13

14

15

16

17

18

19

 The for loop iterates n/k times because it jumps k characters in each iteration. • The ljust operation potentially runs in O(k) time in the worst case, when the last segment of the string is less than k characters

characters across the string s and an ljust operation within each iteration. Here, n is the length of the input string s.

- Therefore, we consider all iterations to get the time complexity: n/k iterations \* O(k) per ljust operation = O(n/k \* k) = O(n).
- So, the overall time complexity of the code is O(n). **Space Complexity:**

The time complexity of the provided code is mainly determined by the list comprehension. It consists of a for loop that runs every k

 The space complexity is determined by the space required to store the output list. Each element of the list is a string of k characters (or fewer if fill characters are added), so the space taken by each element is 0(k).

and needs to be filled with the fill character.

Additionally, the space taken by the input string s does not count towards the space complexity, as it is considered given and not part of the space used by the algorithm.

Thus, the overall space complexity of the code is O(n), where n is the length of the input string s.

• Since there are n/k elements in the list, the total space for the list is O(n/k \* k) = O(n).
