# 1487. Making File Names Unique

find the next suitable suffix to make the name unique.

Here's a step-by-step explanation of how the code works:

dictionary for potential future conflicts.

end of the function.

**Example Walkthrough** 

name.

the newly formed unique name.

Medium Hash Table **Array** String

## **Problem Description**

it should have a unique name. If a name has been used before, a suffix in the format of (k) must be appended, where k is the smallest positive integer that makes the name unique again. The task is to simulate this process and return the final list of names used for the folders.

The problem requires creating a file system with folders named according to the input array names. Whenever a folder is created,

"doc(2)"]. This array represents the names of the folders after every minute following the naming rules defined by the problem.

For instance, if names is ["doc", "doc", "image", "doc(1)", "doc"], the output should be ["doc", "doc(1)", "image", "doc(1)(1)",

Intuition

## The intuition behind the solution involves tracking each folder name and the suffixes applied to resolve the name conflicts. We use a dictionary (hashmap) to keep track of the names and their corresponding suffixes to achieve this efficiently.

We iterate over the input list of names. For each name, we perform the following steps: Check if the name already exists: If the name exists in the dictionary, it means we've encountered a conflict and we need to

Resolve the conflict: Increase the numeral suffix starting from the one recorded in the dictionary until we find a name that is

- not already used. Update the name with the suffix: Once a unique name is constructed, we update the current name in the list of names with
- Update the dictionary: Store the changed name with a suffix of 1 if it's a new name. If the name was altered and had a suffix added, update the original conflicting name's suffix for future conflict resolution.
- The logic behind incrementing the suffix numeral ensures that we will always find the smallest possible integer k to append while

maintaining uniqueness. The defaultdict from the collections module provides convenience for this process since it will

automatically assume the default integer value of 0 when accessing a new name not yet in the dictionary.

tracking the next available integer suffix that should be used for each unique base name.

**Solution Approach** The implementation of the provided solution uses a combination of a loop and a dictionary (hashmap) to achieve its objectives.

Data Structure: We use a defaultdict from the collections module with integer values that defaults to 0. This helps in easily

name.

- **Iterate Through Names:** We iterate over the input list of names with the help of a for loop. Each name encountered is evaluated to determine if it's unique or if a suffix is needed.
- **Check and Resolve Name Conflicts:** • o If the current name is present in the dictionary, it indicates a conflict. We then initiate a while loop to find a unique name by incrementing the integer suffix.

o Inside the loop (while f'{name}({k})' in d), we keep appending a suffix(k) to the original name and increment k to find a non-conflicting

∘ If the current name isn't in the dictionary, it's already unique, and we simply store it with a suffix of 1 (which means d[names[i]] = 1) in the

Return the Modified List: The names list, which now contains all the unique names assigned by the system, is returned at the

update the dictionary with the new suffix (d[name] = k + 1) to indicate the next available suffix for this base name. Final Names Update and Dictionary Maintenance:

• If the name was modified by adding a suffix, we've already updated the entry in the dictionary with the next suffix to be used.

• Once a unique name is found, we assign this new name to the correct position in the names list (using names [i] = f'{name}({k})') and

End of Loop: Each iteration of the loop either adds a unique name directly to the dictionary or resolves a conflict by appending the appropriate suffix. By the end of the loop, all conflicts are resolved.

Start with an empty defaultdict and iterate through the names list.

The iteration ends as there are no more names in the names array.

def getFolderNames(self, names: List[str]) -> List[str]:

# Iterate over all the names in the input list.

names[index] = f'{name}({count})'

# indicating this modified name is now used once.

# Create a dictionary to store the counts of each folder name.

# Check if the name already exists in the dictionary.

# Start with the current count for this name.

# Check if the name with the appended count exists.

# Add or update the name in the dictionary with a count of 1,

# Modify the current name to include the count in the format "name(count)".

# If it does, increment the count and check again.

- This solution's complexity lies in the loop and the operations within it. The average case time complexity is O(n\*k), where n is the length of the names list and k represents the time taken to find a unique name through the incremental suffix process. However, the worst-case time complexity can increase if there is a large number of conflicts that result in longer searches for a unique
- Let's use a small example to illustrate the solution approach. Consider the input array names as ["file", "file", "file",

"file"]. The aim is to create a list where all folder names are unique following the rules described in the problem statement.

First, encounter "file". "file" is not in the dictionary, so we add "file" to the dictionary with a value of 1 (meanwhile it's also added to our final names list). Updated names list: ["file"] Dictionary: {"file": 1}

Next, see another "file". Since "file" is in the dictionary (with a value 1), there's a conflict. We append (1) to "file" to resolve

## Updated names list: ["file", "file(1)"] Dictionary before incrementing: {"file": 1} Increment the suffix in the dictionary: {"file": 2} (for potential future conflicts)

this, resulting in "file(1)".

Updated names list: ["file", "file(1)", "file(2)"] Dictionary: {"file": 3} We see "file" again. Repeat the check and update steps, the suffix this time is (3).

Final names list: ["file", "file(1)", "file(2)", "file(3)"] Final dictionary: {"file": 4}

Encounter another "file". Check the dictionary. Since "file" is there with the value 2, append (2) and increment the suffix.

algorithm successfully solves the file naming problem by systematically ensuring each new folder name has not been used before, appending the smallest possible unique suffix when necessary.

Our final list is ["file", "file(1)", "file(2)", "file(3)"], where each "file" is unique. This shows how the aforementioned

       # Return the list with unique folder names.
        return names
Time and Space Complexity
```

3. If there is a conflict for a name, the code enters into a while loop to find the correct suffix k. In the worst case, it may run as many times as there are names with the same base, let's call this number m. 4. Each iteration of the while loop involves a string concatenation and a dictionary lookup, both of which are 0(1) operations.

**Time Complexity** 

maximum number of duplicates for any name, the worst-case time complexity for while loop iterations across the entire input is O(m\*n) because each unique name will go through the loop at most m times.

The while loop could contribute significantly to the time complexity if there are many names with the same base. If m is the

1. The for loop iterates through each name in the input list, so it gives us an O(n) term, where n is the number of names in the list.

2. Inside the loop, the code checks if name exists in the dictionary with if name in d, which is an O(1) operation due to hashing.

The provided code snippet maintains a dictionary to keep track of the number of times a particular folder name has appeared. It

then generates unique names by appending a number in parentheses if necessary. Let's analyze the time and space complexity:

Therefore, the overall worst-case time complexity is O(n + m\*n) which simplifies to O(m\*n). **Space Complexity** 

The space complexity of the algorithm can be broken down as: 1. The dictionary d, which stores each unique folder name. In the worst case (all folder names are unique, and for each original name, there's a

different number of folders), this dictionary could potentially store 2 entries per name (the original and the latest modified version). So, in the worst case, it could hold up to 2n entries, contributing 0(n) to the space complexity. 2. Temporary storage for constructing new folder names during the while loop does not significantly add to the space complexity because it only

holds a single name at a time.

Therefore, the overall space complexity is O(n).

Time Complexity: 0(m\*n)

To summarize:

Space Complexity: 0(n)
