829. Consecutive Numbers Sum

Math Enumeration Hard

Problem Description

In this problem, we are given an integer n and are required to find the number of ways n can be expressed as the sum of consecutive positive integers. For example, the number 5 can be expressed as 2+3 or 5 alone, which are two ways of writing 5 as the sum of consecutive numbers.

Intuition

The solution to this problem is based on the idea of arithmetic progressions (AP). When you write n as a sum of consecutive numbers, you're essentially creating an arithmetic progression where the common difference is 1. For example, 5=2+3 represents the AP (2, 3), while 9=2+3+4 represents the AP (2, 3, 4), and so on.

We know that the sum of the first k terms of an AP is given by the formula k * (first term + last term) / 2. So, if n is the sumof k consecutive numbers starting from x, we have n = k * (x + (x + k - 1)) / 2. Simplifying this equation, we get 2n = k(2x)

+ k - 1). We look for all pairs (k, x) such that the equation is true. Since both k and x must be positive, k must be less than or equal to 2

times n. We only need to check for k satisfying this constraint. For every positive integer k, we verify whether 2n is divisible by k and whether the resulting start term x is a positive integer by checking (2n/k + 1 - k) % 2 == 0. If these conditions are met,

that means we found a valid group of consecutive numbers that sum up to n, and we increment our answer counter. Each k that satisfies the condition adds to the number of ways n can be expressed as the sum of consecutive positive integers.

The process is continued until k * (k + 1) becomes greater than 2 * n, because larger k would result in non-positive x.

Solution Approach

implementation: Initially, the input n is multiplied by 2 for easier calculation ($n \le 1$). This is because we derived 2n = k(2x + k - 1) and we

integer.

are going to use 2n in our condition checks. We initialize ans to 0, which will hold the number of ways n can be expressed as the sum of consecutive positive numbers,

The solution uses a single while loop, which continues until k * (k + 1) exceeds 2 * n. Here's the breakdown of the

- and k to 1, which represents the length of consecutive numbers starting from x. The while loop runs as long as $k * (k + 1) \le 2 * n$. This is because, for a given k, if k * (k + 1) > 2 * n, x would not be
- positive, as derived from our equation. In other words, k represents the number of terms in the sequence. If the product of k and k+1 (i.e., the sum of an AP where the first term is 1 and the last term is k) is greater than 2n, then x, the starting term, would be less than 1, which is not allowed.
- Inside the loop, we check two conditions for a valid sequence: o 2n % k == 0: This checks if k is a divisor of 2n. If not, it's impossible to express n as the sum of k consecutive numbers. ∘ (2n // k + 1 - k) % 2 == 0: After finding a k for which 2n is divisible, this needs to be true for x to be a positive integer. It's derived from

rearranging and simplifying the equation 2n = k(2x + k - 1); solving for x gives x = (2n/k + 1 - k)/2. This condition ensures that x is an

The loop ends when no more values of k satisfy the condition that $k * (k + 1) \le 2 * n$, at which point we return ans as the

- If both conditions are satisfied, we increment ans by one since we have found a valid grouping. After checking for a k, we increment k by 1 and proceed to check for the next possible sequence length. •
- This approach uses neither additional data structures nor complex algorithms but relies on mathematical properties of numbers and arithmetic progressions.
- **Example Walkthrough**

We want to find out how many different ways we can express 15 as the sum of consecutive positive integers. Let's apply the mentioned solution approach step by step:

• Initialize ans to 0 to keep track of valid expressions, and k to 1 as the potential length of our consecutive numbers starting from some x.

Increment k to 2:

Check if 30 % 2 == 0. Yes.

• Check if 30 % 3 == 0. Yes.

• Begin by doubling n, which gives 2*n = 30.

Now we run the loop as long as $k * (k + 1) \le 2 * n$. For k = 1: • Check if 30 % 1 == 0 (ls k a divisor of 30?). The answer is yes.

Let's walk through an example using the number n = 15 to illustrate the solution approach.

total number of ways n can be represented as the sum of consecutive positive integers.

• Check if (30 // 1 + 1 - 1) % 2 == 0 (Will x be a positive integer?). Simplified, (30 + 1 - 1) % 2 == 0, so yes. Both conditions are met, increment ans to 1.

- Check if (30 // 2 + 1 − 2) % 2 == 0. We have (15 + 1 − 2) % 2 == 14 % 2 == 0. It's true again. • Increment ans to 2.
- Increment k to 3:

• Check if (30 // 3 + 1 − 3) % 2 == 0. We have (10 + 1 − 3) % 2 == 8 % 2 == 0. It's true.

- Increment ans to 3.
- Check if (30 // 5 + 1 5) % 2 == 0. We have (6 + 1 5) % 2 == 2 % 2 == 0. True. • Increment ans to 4.

Increment k to 4:

Increment k to 5:

• 30 % 5 == 0. Yes.

Proceeding like this:

• For k = 6,30 % 6 == 0 but (30 // 6 + 1 - 6) % 2 != 0. It's invalid. • For k = 7,30 % 7 is not 0.

• 30 % 4 is not 0, so k = 4 does not satisfy the condition.

We continue until k * (k + 1) is greater than 30. At k = 8, k * (k + 1) becomes 64, which is greater than 30, so we break the loop.

• ...

sum of consecutive positive integers: 1. 15 alone.

2.7 + 8.

3.4 + 5 + 6.

Python

class Solution:

n <<= 1

count = 0

k = 1

4.1 + 2 + 3 + 4 + 5.

Solution Implementation

def consecutiveNumbersSum(self, n: int) -> int:

Multiply n by 2 for simplifying the (x + x + k - 1) * k / 2 = n equation

Starting with the smallest possible sequence length k = 1

Check if n is divisible by k (for a valid sequence)

Move to the next possible sequence length

// Multiply N by 2 to simplify the calculations below

Initialize the count of ways n can be written as a sum of consecutive numbers

While the sum of the first k consecutive numbers is less than or equal to n

Return the total count of ways n can be expressed as a sum of consecutive numbers

consecutive sequences that sum up to the provided n.

This walkthrough shows a practical application of the described solution approach and how it systematically finds all possible

The value stored in ans at the end of this process will be 4, which means there are four ways to represent the number 15 as the

and if the sequence starting number is a whole number if n % k == 0 and (n // k + 1 - k) % 2 == 0: # If conditions are met, increment the count of possible ways count += **1**

k += 1

return count

Time Complexity

// consecutive positive numbers.

return countOfWays;

return count

positive integers.

Time and Space Complexity

The time complexity of the code is determined by the while loop, which iterates until k * (k + 1) <= n. Since n is doubled at the beginning (n \ll 1), the actual breaking condition for the loop is $k * (k + 1) \ll 2n$.

The given Python code is designed to find the number of ways to express a given positive integer n as a sum of consecutive

We need to find the maximum value of k at which the loop stops. This is when k(k + 1) = 2n, solving for k yields k = sqrt(2n), which is the maximum number of iterations the loop can run. Therefore, the time complexity of the algorithm is O(sqrt(n)).

Space Complexity

The space complexity of the code is 0(1). The reason for this constant space complexity is that the algorithm only uses a fixed number of integer variables (ans, k, and n) which do not scale with the input size. No additional data structures that grow with the input size are used in this algorithm.
