2131. Longest Palindrome by Concatenating Two Letter Words

Counting

Hash Table

String )

## **Problem Description**

**Greedy** Array

Medium

objective is to construct the longest possible palindrome by selecting and concatenating some elements from the given words array. We are allowed to use each element only once. A palindrome is defined as a sequence that reads the same both forwards and backwards. For example, "radar" and "level" are palindromes.

In this problem, we have an array of strings called words. Each string is composed of exactly two lowercase English letters. Our

We are required to return the length of the longest palindrome that can be created. If no palindromes can be formed using the elements of words, the function should return 0.

Intuition

To solve this problem, we need to find pairs of words that can contribute to the palindrome. There are two distinct scenarios to

## consider:

Matching pairs: A pair of words where one is the reverse of the other (e.g., "ab" and "ba"). These can be placed symmetrically on either side of the palindrome. Palindrome pairs: Words that are palindromes in themselves (e.g., "aa", "bb"). They can be placed in the middle of the

- palindrome or paired with themselves to be placed symmetrically. Our strategy is to count the frequency of each word and then iterate over our count dictionary to calculate the contribution of
- each word to the longest palindrome. For each word, we check: If it's a palindrome pair (the word is the same when reversed), we can use it in pairs in the palindrome (e.g., "cc"..."cc" in the
- middle). The count of these words can only contribute in even numbers for both halves of the palindrome. If there's an odd count, one instance can be placed in the middle. If it's a matching pair (word and the reverse are different), we can use as many of these pairs as the minimum count of the
- The primary steps of the solution include: • Counting each word's occurrence using a Counter structure for efficient lookup. Iterating over the unique words and calculating their potential contribution to the palindrome length.
- Based on this logic, the provided solution code computes the longest possible palindrome efficiently.

An additional consideration is that we can only place at most one palindrome word in the very center of the palindrome.

Solution Approach

array. A Counter is essentially a dictionary where each key is an element from the input array and its corresponding value is the

times two v // 2 \* 2 \* 2.

having to explicitly build the palindrome.

word and its reversed pair.

The solution employs a Counter from Python's collections module to efficiently count the occurrences of each word in the words

For every unique word k and its count v in the counter:

potentially be placed in the center of the palindrome.

Return ans as the length of the longest palindrome.

number of times that element appears.

 $\circ$  If the word is a palindrome itself (the same forwards and backwards, i.e., k[0] == k[1]):

• If possible, adding an extra pair of letters if we have leftover palindrome pairs to maximize the palindrome length.

We then iterate through the items in the Counter to determine how each word can contribute to the length of the palindrome. The code consists of a few key steps:

elements that appear an odd number of times.

∘ If the word is not a palindrome and has a complementary word that is its reverse (k[::-1]) in the array: ■ The contribution of such pairs is limited by the lesser count of the pair, hence we use min(v, cnt[k[::-1]]) \* 2.

Initialize two accumulators: ans represents the length of the potential palindrome, and x represents the count of center

■ The half-count of such words v // 2 contributes to both halves of the palindrome. So the contribution would be double the half-count

■ If there's an odd count of a palindrome word ( v & 1), we increment x, because it means we have an instance of this word that can

After iterating through all words, we check if x is greater than 0, which would mean that we have at least one word that can

In summary, by using a counter to track word frequencies and understanding the two types of pairs (matching and palindrome

pairs), we can efficiently calculate the maximum possible palindrome length. The solution is quite elegant as it minimizes the amount of work necessary by directly computing the contribution each word can make to the final palindrome structure without

be placed at the center. If it's possible, add 2 to ans to account for the center element.

**Example Walkthrough** Let's consider a small example to illustrate the solution approach using an array of strings words = ["ab", "ba", "aa", "cc", "cc", "aa"].

• The word "aa" is a palindrome itself and has a count of 2. This means it can contribute twice its half-count (which is 1) to both halves of the

Since both "aa" and "cc" have even counts, there's no additional contribution to the center, so we have x = 0.

Next, we iterate over these counts and calculate how they contribute to the potential palindrome: • The word "ab" has a count of 1. By checking its reverse, we find "ba" also has a count of 1. They can be used as a pair to contribute 2 to the

palindrome length ("ab" + "ba" or "ba" + "ab" on either side).

palindrome, adding 4 to the length ("aa" + "aa" on either side).

Following the solution approach, we first use a Counter to count occurrences:

• The word "cc" is also a palindrome and has a count of 2. It contributes another 4 to the length like "aa" ("cc" + "cc" on either side).

Solution Implementation

from collections import Counter

else:

**if** word[0] == word[1]:

for (String word : words) {

} else {

String word = entry.getKey();

int count = entry.getValue();

central letter pair count += count % 2

// Create a map to store the frequency of each word

Map<String, Integer> wordCount = new HashMap<>();

length\_of\_palindrome += (count // 2) \* 4

Adding together the contributions we get 2 (from "ab" and "ba") + 4 (from "aa") + 4 (from "cc") equals 10, which is the length of the longest palindrome that can be created.

• ab:1

• ba:1

• aa:2

• cc:2

Lastly, since there is no extra odd-count palindrome word to place in the center (x is 0), we don't add anything more to ans.

**Python** 

class Solution:

def longestPalindrome(self, words: List[str]) -> int: # Create a count of all words word count = Counter(words)

length\_of\_palindrome += min(count, word\_count[word[::-1]]) \* 2

// Loop through the array of words to populate the map with word counts

wordCount.put(word, wordCount.getOrDefault(word, 0) + 1);

for (Map.Entry<String, Integer> entry : wordCount.entrySet()) {

// it can potentially be a center of the palindrome

palindromeLength += (count / 2) \* 2 \* 2;

// Count the occurrence of each word in the input vector.

if (word.charAt(0) == word.charAt(1)) {

singleCenter += count % 2;

palindromeLength += singleCenter > 0 ? 2 : 0;

unordered\_map<string, int> wordCount;

int longestLength = 0, middleInserted = 0;

// Create the reverse of the current word.

for (auto& [key, value] : wordCount) {

for (auto& word : words) {

wordCount[word]++;

Therefore, the length of the longest palindrome that can be created from the given words array is 10.

length\_of\_palindrome = central\_letter\_pair\_count = 0 # Counter items() contains pairs of (word, count) for word, count in word count.items(): # Check if the word is a pair of identical letters, like "aa"

# Count of such word pairs that can be used as the central part of the palindrome

# For other pairs, add the minimum count of the pair and its reverse pair to the length

# If there are pairs of identical letters, we could place exactly one in the center of the palindrome

# Add the count (rounded down to the nearest even number) times 2 to the length

- length\_of\_palindrome += 2 if central\_letter\_pair\_count else 0 return length\_of\_palindrome
- Java class Solution { public int longestPalindrome(String[] words) {
  - // Initialize variables to store the length of palindrome formed and a flag for center character allowance int palindromeLength = 0, singleCenter = 0;

// If the word is the same as its reversed version and has two identical characters,

// Check if there's an odd count, if so one instance can be used as a center

// Add the even part into the palindrome length (doubled, as palindromes are symmetric)

// If there is at least one single center word, add 2 to the length for the center character of palindrome

// If the word is not its own reversed, pair it with its reverse occurrence count

palindromeLength += Math.min(count, wordCount.getOrDefault(reversedWord, 0)) \* 2;

## word count = Counter(words) length\_of\_palindrome = central\_letter\_pair\_count = 0 # Counter.items() contains pairs of (word, count) for word, count in word count.items():

class Solution:

});

Constructing the Counter object from the words list. This operation has a time complexity of O(n), where n is the number of words in the input list, since it has to count the occurrences of each unique word.

that would increase the order of complexity beyond linear.

The time complexity of the code is determined by a few factors:

For each word, we may check for its reverse in the counter. This is a constant time operation 0(1) given the nature of hashmaps (dict in Python).

Iterating over the items in the counter. In the worst case, each word is unique, so this operation could iterate up to n times.

- Therefore, the time complexity of the loop is also O(n). Adding the contributions from these operations, the overall time complexity is 0(n). There is no nested iteration or operations
- The Counter object stores elements as keys and their counts as values. In the worst case, every word in words is unique, which means the Counter will store n keys and values. Hence, space complexity for the Counter is O(n).

contribute a constant space overhead which does not depend on the input size.

The integer variables ans and x use a constant amount of space, 0(1). So, the overall space complexity of the function is O(n) due to the space taken by the Counter object. All other variables only

Therefore, the final space complexity is O(n).

The space complexity of the code is primarily affected by the storage requirements of the Counter object:
