# 2495. Number of Subarrays Having Even Product

Medium Array **Math Dynamic Programming** 

### **Problem Description**

number. A subarray is defined as a contiguous part of the original array. Since the array is 0-indexed, the first element is at position 0. Remember, a single element is also considered a subarray, so if any element in the array is even, that alone counts as one subarray with an even product. The final output should be the total count of such subarrays.

We are tasked with finding the number of subarrays from a given array nums, where the subarrays have a product that is an even

## Intuition

With this in mind, we scan the array and keep track of the last position last where we encountered an even number. When we find an even number, we know that all subarrays that end at that position and start before or at the last found even number's position will have an even product. For every element v at index i, if v is odd, the number of subarrays ending at i with an even product is the same as the number of

To solve this problem, we can use the fact that the product of integers is even if and only if at least one of the integers is even.

subarrays ending at i-1. If v is even, then all subarrays ending at i have an even product. We add 1 to account for the current element, which is a subarray itself if it's even. We keep on adding this quantity to a cumulative answer variable ans. This approach avoids the need to check the product of each subarray individually, which would not be efficient for large arrays,

and instead uses the properties of even/odd numbers to count the subarrays in a linear pass through the array. **Solution Approach** 

#### The solution is implemented in Python using a single pass through the array. The algorithm can be broken down into the following steps:

Initialize two variables, ans and last. ans will hold the final result — the number of subarrays with an even product. last will store the index of the most recently found even number in the array. Initially, last is set to -1 to indicate that we haven't

- encountered any even numbers yet. Iterate through nums using a loop, where i is the current index, and v is the value of the current element:  $\circ$  Inside the loop, check if the current element v is even (using v % 2 == 0). If it is, Update last to the current index i because we now have a new last index where the subarray with an even product can start.
- Regardless of whether the current element is even or odd, update ans by adding last + 1 to it. The last + 1 represents the number of
  - subarrays ending at i that include an even number and thus have an even product. This works because:
  - If v is even, all subarrays ending at i will have an even product. The number of such subarrays is i + 1 (since arrays are 0-indexed). ■ If v is odd, the subarrays that have an even product are those which start before or at the last even number found. That's why we
  - increment ans by last + 1 instead of i + 1. Return the value of ans once the loop is completed.
- The algorithm relies on simple arithmetic and control structures and does not use any specific data structure or complex pattern. It merely exploits the mathematical properties of multiplication (an even number times any other number is always even) to count

the input array, because it processes each element of the array only once. **Example Walkthrough** 

This approach does not explicitly construct each subarray; instead, it calculates the number of valid subarrays ending at a certain

point based on knowledge of earlier components of the array. This is why the algorithm runs in O(n) time, where n is the length of

## Here is a step-by-step explanation of how we would apply the algorithm:

nums = [3, 2, 5, 6, 7]

the subarrays efficiently.

We begin iterating through nums:

```
ans = 0, indicating no subarrays ending here have an even product.
```

We start by initializing ans to 0 and last to -1 because we haven't encountered any even numbers yet.

Let's illustrate the solution approach using a small example. Consider the following input array:

resulting in ans += (1 + 1) which gives us ans = 2. This accounts for two subarrays [2] and [3, 2].

within the array [3, 2, 5, 6, 7].

Index 2: The value 5 is odd, so last remains at 1. We update ans by adding last + 1 to it, resulting in ans += (1 + 1) which gives us ans = 4. The subarrays [2, 5] and [3, 2, 5] are the new subarrays added to the count.

Index 0: The value 3 is odd. We do not update last, but we still update ans. Since last is -1, ans += (last + 1) results in

Index 1: The value 2 is even, so we update last to the current index (last = 1). For updating ans, we add last + 1 to it,

ans += (3 + 1) which gives us ans = 8. The new subarrays considered here are [6], [5, 6], [2, 5, 6], and [3, 2, 5, 6].

Index 3: The value 6 is even, so we update last to the current index (last = 3). We now add last + 1 to ans, resulting in

Index 4: The value 7 is odd, so last does not change and remains at 3. We update ans once again by adding last + 1 to

it, resulting in ans += (3 + 1) which brings us to ans = 12. The new subarrays considered are the extensions of previous subarrays ending with 7. Once the loop is completed, we have our final answer. The value of ans is 12, so there are 12 subarrays with an even product

In this example, each step either adds a new set of subarrays ending with an even number or extends the existing subarrays with

an odd number, while keeping track of the total count with the ans variable. This linear algorithm is efficient and takes into

each possible subarray explicitly. Solution Implementation

account the characteristics of even and odd products to dynamically calculate the total amount without the need to enumerate

# and last\_even\_index to keep track of the last seen even number index  $sum_even_products$ ,  $last_even_index = 0$ , -1# Iterate over the list of numbers with index and value

def evenProduct(self, nums: List[int]) -> int:

           sum_even_products += last_even_index + 1
       # Return the accumulated sum of counts of subarrays with an even product
       return sum_even_products
Time and Space Complexity
  The given Python code defines a method evenProduct that calculates the sum of the indices of the last even number seen in a list
```

# of integers up to each element in the list.

**Time Complexity** The time complexity of the code is O(n), where n is the length of the input list nums. This is because the code contains a single

loop that iterates through the list nums. During each iteration, the code performs a constant-time check to determine whether an

#### element is even (i.e., v % 2 == 0), and it updates two variables, last and ans, with simple arithmetic operations, which also take constant time.

**Space Complexity** The space complexity of the code is 0(1) because the extra space used by the algorithm is constant and does not depend on the size of the input list. The variables ans and last are used for storing the running total and the index of the last encountered even

number, respectively, and their space usage does not scale with the input size.
