2095. Delete the Middle Node of a Linked List

Problem Description

You have a singly linked list. Your task is to remove the node that is in the middle of this list and return the head of the updated list. The middle node is defined as the ⌊ n / 2⌋ th node from the beginning of the list, where n is the total number of nodes in the list and ⌊ x⌋ signifies the greatest integer less than or equal to x. This means that you're not counting from 1, but from 0. So, in a linked list with:

Leetcode Link

2 nodes, the middle is the 1st node.

1 node, the middle is the 0th node.

- 3 nodes, the middle is the 1st node. 4 nodes, the middle is the 2nd node.
- 5 nodes, the middle is the 2nd node.
- Your goal is to efficiently find and remove this middle node and ensure the integrity of the linked list is maintained after the removal.

Intuition

To solve this problem, the two-pointer technique is a perfect fit. The idea is to have two pointers, slow and fast. The slow pointer moves one step at a time, while the fast pointer moves two steps at a time. By the time the fast pointer reaches the end of the list,

the slow pointer will be at the middle node. Here's the step-by-step intuition:

1. Initialize a dummy node that points to the head. This dummy node will help us easily handle edge cases like when there's only one

2. Start both slow and fast pointers. The slow pointer will start from the dummy node, while fast will start from the head node of

node in the list.

- the list. 3. Move slow one step and fast two steps until fast reaches the end of the list or has no next node (this is for cases when the
- number of nodes is even). 4. When the fast pointer reaches the end of the list, the slow pointer will be on the node just before the middle node (since it started from dummy, which is before the head).
- 6. Return the new head of the list, which is pointed to by dummy next, since the dummy node was added before the original head. By utilizing this approach, we can identify and remove the middle node in a singly linked list in a single pass and O(n) time
- complexity, where n is the number of nodes in the list.

5. Adjust the next pointer of the slow node so that it skips over the middle node, effectively removing it from the list.

The solution utilizes a two-pointer approach, which is a common technique for problems involving linked lists or arrays where elements need to be compared or modified based on their positions. Here's a detailed walk-through:

the list.

pointer. Inside the loop:

the previous node.

Solution Approach

2. Two-Pointers: Two pointers are defined: slow starting at the dummy node and fast at the head node. This offset will allow slow to reach the node just before the middle node by the time fast reaches the end.

1. Initialization: A dummy node is created and set to point to the head of the list. The dummy node, not present in the original list,

serves as a starting point for the slow pointer, and helps in case the list has only one node, or if we need to delete the head of

 The slow pointer is moved one node forward with slow = slow.next. The fast pointer is moved two nodes forward with fast = fast.next.next. 4. **Deletion**: After the loop, slow is at the node just before the middle node. To delete the middle node, slow.next is updated to

point to slow.next.next. This effectively removes the middle node from the list by "skipping" it, as it is no longer referenced by

3. Traversal: The traversal begins with a while loop that continues until fast is neither null nor pointing to a node with a null next

head pointing to the actual head of the list and its next pointer reflects the head of the updated list post-deletion. The key data structure used is the singly-linked list, which is manipulated using pointer operations. This solution ensures that the

5. Return Updated List: Finally, the head of the updated list is returned, which is dummy next. This is because dummy is a pseudo-

- middle node is deleted in a single pass, with a time complexity of O(n), where n is the number of nodes in the list. There is a constant space complexity of O(1), as the number of new variables used does not scale with the input size.
- Example Walkthrough Let's illustrate the solution approach using a small example. Suppose we have the following linked list:

1 [A] -> [B] -> [C] -> [D] -> [E] We want to remove the $\{lightimes lightimes floor; light$

Step 2: Two-Pointers

Step 1: Initialization

Step 3: Traversal

slow

Step 4: Deletion

9

10

Second iteration:

Following the solution approach:

We set the slow pointer to [X] (dummy node) and the fast pointer to [A] (head node).

We create a dummy node [X] and point it to the head of the list [A].

The list now looks like this: [X] -> [A] -> [B] -> [C] -> [D] -> [E].

We start moving both pointers through the list with the loop condition in mind.

```
First iteration:
   [X] \rightarrow [A] \rightarrow [B] \rightarrow [C] \rightarrow [D] \rightarrow [E]
```

slow

Third iteration (fast.next is null):

The final updated list looks like this:

1 [A] -> [B] -> [D] -> [E]

self.val = val

self.next = next

 $[X] \rightarrow [A] \rightarrow [B] \rightarrow [C] \rightarrow [D] \rightarrow [E]$

[X] -> [A] -> [B] -> [C] -> [D] -> [E] slow 14 fast (end of list)

Now that fast has reached the end of the list, slow is just before the node we want to delete ([C]).

• We perform the deletion by updating the next pointer of the slow node to skip [C] and point to [slow.next.next].

fast

```
Before deletion:
    [X] \rightarrow [A] \rightarrow [B] \rightarrow [C] \rightarrow [D] \rightarrow [E]
                               f
slow.next (to be deleted)
  After deletion:
     [X] -> [A] -> [B] -----> [D] -> [E]
8
                         slow
                                                      slow.next
9
Step 5: Return Updated List

    We return the head of the updated list, which is dummy.next.
```

Node [C] has been removed, and the integrity of the list is maintained.

def deleteMiddle(self, head: Optional[ListNode]) -> Optional[ListNode]:

Create a dummy node that points to the head of the list, to handle edge cases smoothly

Now, slow_pointer is at the node just before the middle one. Delete the middle node

Return the head of the updated list, by skipping over the dummy node

// Return the modified list. The dummy's next points to the new list's head.

Initialize two pointers, slow will move one step at a time, fast will move two steps at a time

* If the list is empty or has only one node, returns null.

function deleteMiddle(head: ListNode | null): ListNode | null {

* @param head - The head node of the singly linked list.

slow = slow.next; // Move 'slow' one step.

fast = fast.next.next; // Move 'fast' two steps.

// Return the modified list with the middle node removed.

* If the list has an even number of nodes, it removes the second of the two middle nodes.

// If the list is empty or has only one node, it means there is no middle to delete.

// 'slow' is now behind the middle node, so set its 'next' to skip the middle node.

* @returns The head node of the modified list with the middle node removed.

return head;

Time Complexity The provided code implements an algorithm to delete the middle node of a singly-linked list. The while loop iterates through the list with two pointers: slow moves one step at a time, and fast moves two steps at a time. This loop will continue until fast (or its successor fast next) reaches the end of the list. This means that we traverse the list only once, which leads to a time complexity of O(N), where N is the number of nodes in the singly-linked list.

Space Complexity

The algorithm uses a few constant extra variables: dummy, slow, and fast. Regardless of the size of the list, the space used by these variables does not increase. Therefore, the space complexity of the algorithm is 0(1), indicating that it uses a constant amount of additional space beyond the input list.
