1946. Largest Number After Mutating Substring

Problem Description

String Medium Greedy Array

In this problem, you have a string num that represents a large integer and an array change of ten integers, where each index of the array corresponds to a digit from 0 to 9. The value at each index d in the array is the digit that d should be mapped to. You are allowed to mutate a single contiguous substring of num by replacing each digit in it according to the mapping defined by the change possible. To make it clearer, mutating a substring means selecting a continuous sequence of digits in num and replacing each of those

Leetcode Link

array. The goal is to perform this operation in such a way that the resulting integer, when converted back to a string, is as large as digits with their corresponding digit from the change array. You can also choose not to mutate any substring at all. A substring here means any contiguous sequence of characters within the string num. Intuition

corresponding digit in change. Once you start mutation, continue to mutate sequentially as long as the digits can be increased or stay the same after replacement. If at any point, a subsequent digit cannot be increased through mutation (i.e., the digit in num is greater than the mapping digit in change), then stop the mutation process because continuing would result in a smaller number. The reasoning for starting at the earliest possible digit is to take advantage of the positional value in numbers: a digit towards the

To get the largest possible number after mutation, one should start mutating the earliest digit in num that can be increased by the

left has more value than a digit towards the right. Thus, to maximize the number, we want to increase the value of the leftmost possible digits. Moreover, at the first occurrence where mutating does not increase the number anymore, we should stop. This strategy ensures we get the highest value after a single substring mutation. The given solution implements this approach by:

Converting the string num into a list of characters s for easy manipulation.

- 2. Iterating through this list and checking, at each index, if the digit can be increased via mutation.
- 3. If a digit can be increased, mutating the current digit and continuing to the next digit until a digit is found that would not be increased by mutation, at which point the loop breaks.
- 4. After the loop, the possibly mutated list of characters s is joined back together to form a string representing the largest possible integer after mutation.
- Solution Approach

The algorithm uses a simple linear scan to implement the intuitive approach. Here's how the code executes the solution:

1. First, the string num is converted into a list of characters s, which allows for indexed access and in-place modification of the individual digits.

- 2. The algorithm then enters a loop, iterating over each digit in the list s. For each digit at index i, it is cast to an integer and compared against the digit it would map to in the change array.
- number. The while loop is then entered to continue mutation as long as the criterion is met (i.e., the digit at the current index is less than or equal to the corresponding digit in the change array):

3. If the digit from the change array is greater than the current digit in s, this means we can "mutate" this digit to get a larger

1 while i < len(s) and int(s[i]) <= change[int(s[i])];</pre> s[i] = str(change[int(s[i])])

```
4. The mutation starts at the current index 1 and continues to the subsequent digits as long as they are less than or equal to their
  mapped counterparts in the change array. This ensures that the number is strictly increasing or staying the same as we continue
```

patterns are needed—just simple conditional logic and iteration.

step explanation to illustrate how the solution approach would work on this example:

would otherwise require additional space.

- the mutation. 5. Once a digit is encountered where the change array does not provide a greater or equal digit, the while loop is exited (intuitively, mutation ends), and the outer for loop is also exited with a break statement. This ensures we are only mutating one contiguous
- 6. The list is joined back into a string with return ''.join(s), providing the mutated (or unmutated, if no mutation took place) number as the output. In this approach, the data structure used is a list for s, which allows modifications to be made. No complex algorithms or data
- String manipulation happens in place within the list of characters, which avoids the need for creating additional strings during the process. This is efficient in terms of space usage, since strings in Python are immutable and creating substrings or modifying strings

The linear scan enforces that the loop runs with a complexity of O(n), where n is the length of num. This makes the algorithm efficient because it scans each digit only once and performs in-place mutations without the overhead of additional string manipulation functions.

Example Walkthrough

Let's say we are given the string num = "132" and the change array change = [9, 8, 5, 0, 3, 2, 1, 2, 6, 4]. Here is a step-by-

1. Convert num to a list s of characters for manipulation:

substring.

1 s = ['1', '3', '2']

- 3. For the first digit in s, '1', the corresponding digit in the change array is change [1] = 8. Since 8 is greater than 1, we can mutate this digit:
- 4. Continue to the next digit, '3'. The corresponding digit in the change array is change [3] = 0. Since 0 is not greater than 3, we

1 s = ['8', '3', '2'] // The first digit is mutated to '8'

2. Start iterating from left to right over each character in s.

should stop mutating. However, we should check if the new digit is the same or greater to allow the mutation to continue, but in our case, it's not, so we stop.

5. The algorithm would have ideally continued mutating if the change digits were greater than or equal to the current digits in s, but

since the digit 3 would decrease if we mutate it using the change array, the mutation process ends.

1 result = '832'

And that's the final answer. We obtain the largest possible number after mutating the string num with the given change array using

Python Solution

if digit_mappings[int(char)] > int(char):

until no further changes are beneficial

only one continuous substring which, in this case, was just the first digit.

def maximumNumber(self, num: str, digit_mappings: List[int]) -> str:

Convert the number string to a list of characters for easy manipulation

6. Finally, the list s is joined to form a string, giving us the result:

Traverse through the number's characters for index, char in enumerate(num_list): # Determine if the current digit can be increased using the provided mapping

while index < len(num_list) and int(num_list[index]) <= digit_mappings[int(num_list[index])]:</pre>

If it can, change the current digit and continue changing subsequent digits

num_list[index] = str(digit_mappings[int(num_list[index])])

```
14
                       index += 1
                   # Once a change is not beneficial, break the loop as no further checks are necessary
15
16
                   break
17
           # Join the characters back into a string and return the result
```

1 // This method returns the maximum number by swapping digits as per the change array.
    function maximumNumber(numStr: string, change: number[]): string {
       let numLength = numStr.length; // Store the length of the input number string
       // Convert the string to an array of characters for easy manipulation
       let numArr = numStr.split('');
       // Iterate over each digit of the number array
       for (let i = 0; i < numLength; ++i) {</pre>
           // Parse the current character to get the digit
10
           let digit = parseInt(numArr[i], 10);
11
           // Check if the current digit can be increased by using the change array
13
           if (change[digit] > digit) {
14
               // Keep swapping until the change array offers a digit greater than or equal to the current one
15
               while (i < numLength && change[digit] >= digit) {
16
                   // Perform the swap by updating the character in the array
17
                   numArr[i] = change[digit].toString();
                   ++i; // Move to the next digit
19
20
                   if (i < numLength) {</pre>
21
                       // Update the digit if we are not at the end of the array
                       digit = parseInt(numArr[i], 10);
23
24
26
               // Once we cannot swap anymore, break out of the loop as the string is now maximized
27
               break;
28
29
30
       // Join the array of characters back into a string to get the modified number
       return numArr.join('');
34
35 // Example usage:
  // const result = maximumNumber("132", [9, 8, 5, 0, 3, 4, 2, 1, 9, 8]);
```

// console.log(result); // Output should be "832" after applying the change array. 38

Time and Space Complexity

31 32 33 }

through the characters of the string once, starting from the beginning of the string. The inner while loop runs only when a digit can be changed to a higher digit based on the change array, and it runs at most n times in total, not n times for each character, since the loop breaks once no more changes can be done. Therefore, in the worst-case scenario, each character is evaluated once, and the

change is applied within the same iteration without causing another full scan of the string.

Space Complexity

increase the space complexity.

Time Complexity The time complexity of the given code is O(n), where n is the length of the string num. The code consists of a single loop that goes

The space complexity is O(n), where n is the length of the input string num. This is due to the conversion of the input string num to a list s, which creates a separate array of characters of size n. Other than that, there are no significant data structures used that would
