# 857. Minimum Cost to Hire K Workers

Sorting **Heap (Priority Queue)** Greedy Array Hard

# **Problem Description**

The quality of a worker represents a numerical value for the worker's skill level, while the wage indicates the minimum salary that the worker expects. To form a paid group, exactly k workers need to be hired under two constraints:

In this problem, you are responsible for hiring a group of n workers. Each worker has two associated parameters: quality and wage.

1. The payment of each worker must be proportional to their quality relative to the other workers in the group. This means if one

- worker has twice the quality compared with another worker in the group, they should also be paid twice as much. 2. No worker can be paid less than their minimum wage expectation.
- conditions are satisfied.

Intuition The solution involves the concept of 'efficiency', which in this context is defined as the ratio of wage to quality for each worker. The

The goal is to calculate the minimum amount of money required to hire exactly k workers such that both of the aforementioned

### intuition is to first sort the workers by their efficiency. This allows us to consider the workers in order of how much wage they require per unit quality.

Once sorted, the algorithm uses a min-heap to keep track of the k workers with the largest qualities, since any payment must be at least as large as the k-th worker's quality times the efficiency. By iterating through the sorted workers and maintaining the sum of the largest k qualities, when the k-th worker is added to the heap, the smallest ratio that satisfies all the workers' minimum wage

expectations can be calculated. This is done by multiplying the total sum of the chosen qualities by the current worker's efficiency.

During iteration, the algorithm keeps updating the answer to record the least amount of money needed to form a paid group. This is

achieved by maintaining a total quality sum and updating it as the group changes. When a new worker is added and the group exceeds k workers, the worker with the highest quality (and therefore the one contributing most to the total wage) is removed from the heap and the total quality sum. This step ensures that the maintained group always has k workers. The answer is updated whenever a potentially lower total wage for the group is found.

The use of a heap allows efficient removal of the worker with the highest quality in O(log k) time and helps to maintain the total quality sum and minimum possible wage for the group at each step. Solution Approach The implementation of the solution provided in Python involves a sorting step and the use of a min-heap. The overall approach

by-step explanation of how the solution works: 1. Sorting: We start by computing the efficiency for each worker, which is the ratio of wage[i] to quality[i]. Then, we sort the

follows an efficient algorithm to minimize the total wage based on the ratio of wage to quality defined as efficiency. Here's a step-

workers based on this efficiency in ascending order. This ensures that we consider workers in increasing order of how much

## they expect to be paid relative to their quality. 2. Initializing the Heap: We use a min-heap (in Python, a min-heap can be utilized by pushing negative values into it) to keep track

of the k largest qualities encountered thus far in the sorted array. A heap is advantageous here because it allows us to efficiently retrieve and remove the worker with the highest quality, which in turn affects the total payment calculation. 3. Iterative Calculation: Next, we iterate through the sorted workers and do the following:

Add the current worker's quality to the total quality sum (tot).

The space complexity is O(n) to store the sorted efficiencies and the heap.

Suppose we have 4 workers, each with the following quality and wage expectations:

For worker 1, quality = 10. We add it to tot and push -10 to the heap.

get away with to hire k = 2 workers while meeting the constraints is ans = 180.

self, quality: List[int], wage: List[int], k: int

# Pair each worker's quality with their minimum wage

# and sort the workers based on their wage-to-quality ratio.

# Initialize the answer as infinity to be later minimized

workers = sorted(zip(quality, wage), key=lambda x: x[1] / x[0])

# Initialize the total quality of workers hired so far as zero

# and removes the biggest quality from the total

total\_quality += heapq.heappop(max\_heap)

// Create Worker instances combining both quality and wage.

// Sort the workers based on their wage-to-quality ratio.

// Add the current worker's quality to the total.

// Add the current worker's quality to the max heap.

// Use a max heap to keep track of the highest quality workers.

PriorityQueue<Integer> maxHeap = new PriorityQueue<>((a, b) -> b - a);

// Iterate through the sorted workers by increasing wage-to-quality ratio.

int totalQuality = 0; // Tracks the total quality of hired workers.

Arrays.sort(workers, (a, b) -> Double.compare(a.wageQualityRatio, b.wageQualityRatio));

double minCost = Double.MAX\_VALUE; // Initialize minimum cost to a large number.

// If we have enough workers (exactly k), we can try to form an answer.

// Calculate the cost based on current worker's wage-to-quality ratio.

// Remove the worker with the highest quality (to maintain only k workers).

minCost = Math.min(minCost, totalQuality \* worker.wageQualityRatio);

workers[i] = new Worker(quality[i], wage[i]);

for (int i = 0; i < numWorkers; ++i) {</pre>

for (Worker worker: workers) {

totalQuality += worker.quality;

maxHeap.offer(worker.quality);

totalQuality -= maxHeap.poll();

return minCost; // Return the minimum cost found.

if (maxHeap.size() == k) {

worker 3 and the new worker 4 in our consideration).

becomes min(180, 6 \* 45) = 270.

C++ Solution

1 #include <vector>

) -> float:

def mincostToHireWorkers(

min\_cost = float('inf')

total\_quality += q

if len(max\_heap) > k:

total\_quality = 0

represents the efficiency of the last worker added to meet the group size of k.

workers while satisfying the constraints. We return ans as the solution to the problem.

 Push the negative of the current worker's quality to the heap to maintain the k largest qualities. o If the heap size exceeds k, it means we have more than k workers in the current group, so we pop from the heap (which removes the worker with the highest quality from our consideration) and reduce our total quality sum accordingly. If the heap size is exactly k, we calculate the current cost to hire k workers based on the worker with the current efficiency

4. Returning the Result: After going through all workers, the variable ans stores the minimum amount of money needed to hire k

and update the answer with the minimum cost observed so far. This is done by ans = min(ans, w / q \* tot), where w / q

subset selection - in this case, maintaining a subset of workers of size k with the greatest quality. Algorithm Complexity: The time complexity of this algorithm is mainly governed by the sorting step, which is 0(n log n), where n is the number of workers. Operating on the heap takes O(log k) time for each insertion and deletion, and since we go through the

workers once, the overall complexity for heap operations is  $0(n \log k)$ . Hence, the total time complexity is  $0(n \log n + n \log k)$ .

The key patterns used in this solution include sorting based on a custom comparator (efficiency), and utilizing a heap for dynamic

**Example Walkthrough** Let's walk through the solution with a small example.

We want to hire k = 2 workers while meeting the conditions specified in the problem. Step 1: Sorting First, we calculate the efficiency wage[i] / quality[i] for each worker: 1 Efficiency: 6 6 6

Notice that in this case, all workers have the same efficiency, meaning any order keeps them sorted by efficiency. However, this

Step 3: Iterative Calculation We iterate through the sorted workers, keeping track of the total quality (tot) and potential total wage

• The heap size is now equal to k, so we calculate the total payment for these k workers using the current efficiency, which is 6 \*

### Step 2: Initializing the Heap Now we initialize a min-heap to keep track of the largest qualities as we iterate through the workers. Initially, the heap is empty.

(ans).

won't always be the case.

Workers:

Wage:

Quality:

10 20 15 30

60 120 90 180

tot = 180. We set ans = 180. To consider other possible combinations since the heap size now exceeds k, we must pop from the heap:

• For worker 2, quality = 20. We add it to tot, giving us tot = 30, and push -20 to the heap.

• Since the heap is a min-heap with negatives, when we pop, we're removing the worker with the highest quality, in this case -10 (worker 1), leaving the heap with -20 and tot = 20. • We then move to worker 3, with quality = 15. Adding to tot gives us 35, and we push -15 to the heap.

We proceed like this until all workers have been considered. Step 4: Returning the Result After evaluating all possible groupings of k workers, we find that the minimum total payment we can

This is a very simplified example for clarity, where efficiencies were all equal. In practice, efficiencies would vary, and the sorting

step would play a critical role in determining which workers could potentially be hired together within budget constraints.

• We must update ans if it gets lower. Worker 4 gets added with an efficiency of 6 and quality = 30. The new tot is 45, and ans

• The heap size again exceeds k, so we pop the largest quality, which is now -20 (worker 2), and tot becomes 15 (as we keep

import heapq from typing import List

# If we have more than k workers, remove the one with the highest quality

# Since we stored negative qualities, popping from heap retrieves

 $max_heap = []$ 19 20 21 # Iterate over each worker 22 for q, w in workers: 23 # Add the current worker's quality to the total quality

heapq.heappush(max\_heap, -q)

# Max heap to store the negative of qualities,

# since heapq in Python is a min heap by default

# Push the negative quality to the heap

```
# If we've collected a group of k workers
35
               if len(max_heap) == k:
36
                   # Calculate the current cost for this group of workers, which is
37
                   # the wage-to-quality ratio of the current worker times total quality
                   # and update the minimum cost if it's less than the previous minimum
38
                   min_cost = min(min_cost, w / q * total_quality)
39
40
41
           # Return the minimum cost found to hire k workers

Time and Space Complexity

if (qualityMaxHeap.length > k)

complexity of  $O(n \log n)$  where n is the number of workers.

The time complexity of the code consists of several components:

2. Heap Operations: For each worker in the sorted list, the algorithm performs heap push (heappush) and possibly heap pop (heappop) operations when the heap size is equal to k. Pushing onto the heap has a time complexity of O(log k) and popping from the heap also has a complexity of  $O(\log k)$ .

1. Sorting: The list t is sorted based on the ratio of wage to quality using Python's built-in sort function, which has a time

Given there are n workers, and therefore n heappush operations, and at most n heappop operations when the heap size reaches k, the heap operations give us a total time complexity of  $O(n \log k)$ .

So, the overall time complexity is the sum of the sorting complexity and the heap operations complexity: 0(n log n + n log k). Space Complexity

1. Sorted List: The sorted list t takes O(n) space since it contains a tuple for each worker. 2. **Heap**: The heap h can store up to k elements, so it has a space complexity of O(k).

The space complexity is determined by the extra space used by the heap and the sorted list:

Therefore, the total space complexity is the sum of the space complexities for the sorted list and the heap, which is 0(n + k).
