# **Problem Description**

edges given in a list where each edge is represented by a pair of nodes like [a, b] that signifies a bidirectional (undirected) connection between node a and node b. Our main objective is to determine if the given graph constitutes a valid tree. To understand what makes a valid tree, we should recall two essential properties of trees:

In this problem, we're given a graph that is composed of 'n' nodes which are labeled from 0 to n - 1. The graph also has a set of

1. A tree must be connected, which means there should be some path between every pair of nodes.

- 2. A tree cannot have any cycles, meaning no path should loop back on itself within the graph.
- Therefore, our task is to check for these properties in the given graph. We need to verify if there's exactly one path between any two

conditions are met, we return true; otherwise, we return false. Intuition

nodes (confirming a lack of cycles) and that all the nodes are reachable from one another (confirming connectivity). If both

### To determine if the set of edges forms a valid tree, the "Union Find" algorithm is an excellent choice. This algorithm is a classic approach used in graph theory to detect cycles and check for connectivity within a graph.

Here's why Union Find works for checking tree validity:

1. Union Operation: This is used to connect two nodes. If they are already connected, it means we're trying to add an extra

connection to a connected pair, indicating the presence of a cycle. 2. Find Operation: This operation helps in finding the root of each node, generally used to check if two nodes have the same root.

- If they do, a cycle is present since they are already connected through a common ancestor. If not, we can perform an union operation without creating a cycle.
- 3. Path Compression: This optimization helps in flattening the structure of the tree, which improves the time complexity of subsequent "Find" operations. In our solution, we start with each node being its own parent (representing a unique set). Then, we iterate through each edge,
- If they do, we've detected a cycle and return false as a cycle indicates it's not a valid tree. • If they don't, we connect (union) them by updating the root of one node to be the root of the other.

As we connect nodes, we also decrement 'n' as an additional check. If at the end of processing all edges, there's more than one disconnected component, 'n' will be greater than 1, indicating the graph is not fully connected, thus not a valid tree. If 'n' is exactly 1,

**Solution Approach** 

it means the graph is fully connected without cycles, so it's a valid tree and we return true.

applying the "Find" operation to see if any two connected nodes share the same root:

The solution provided leverages the Union Find algorithm to check the validity of a tree. Here's a step-by-step walkthrough of the algorithm as implemented in the Python code: 1. Initialization:

#### i from 0 to n-1. The variable n tracks the number of distinct sets or trees; initially, each node is separate, so there are n trees.

3. Process Edges:

2. Function Definition - find(x): This function is critical to Union Find. Its purpose is to find the root parent of a node x.

along the search path directly to the root. This helps reduce the tree height and optimize future searches.

• The function is implemented with path compression, meaning every time we find the root of a node, we update the parent

We start by creating an array p to represent the parent of each node. Initially, each node is its own parent, thus p[i] = i for

We iterate over each edge in the list edges.

parent of find(a) to find(b).

thus forming a cycle. In this case, we immediately return False, as a valid tree cannot contain cycles. o If the roots are different, it means that connecting them doesn't form a cycle, so we perform a union operation by setting the

connectivity. The solution runs in near-linear time, making it very efficient for large graphs.

Let's consider a simple example to illustrate the solution approach using the Union Find algorithm.

For each edge [a, b], we find the roots of both nodes a and b using the find function.

 After successfully adding an edge without forming a cycle, we decrement n since we have merged two separate components into one. 4. Final Verification:

We check if the roots are equal. If they are, find(a) == find(b), this indicates that nodes a and b are already connected,

component without cycles, which satisfies the definition of a tree. o If n is not 1, it means the graph is either not fully connected, or we have returned False earlier due to a cycle. In either case, the graph does not form a valid tree.

The simplicity of this algorithm comes from the elegant use of the Union Find pattern to quickly and efficiently find cycles and check

• After processing all edges, we check if n is exactly 1. If it is, it means all nodes are connected, forming a single connected

Suppose we have a graph with n = 4 nodes labeled from 0 to 3, and we're given an edge list edges = [[0, 1], [1, 2], [2, 3]]. Step 1: Initialization

## • We define the find function to find the root parent of a given node x. Additionally, this function uses path compression. **Step 3: Process Edges**

Step 2: Function Definition - find(x)

**Example Walkthrough** 

perform the union operation by setting p[1] to the root of 0 (which is 0). Now p = [0, 0, 2, 3], and we decrement n to 3.

root of 1 (which is 0). Now p = [0, 0, 0, 3], and we decrement n to 2.

Our parent array is now p = [0, 0, 0, 0], and n is decremented to 1.

def validTree(self, num\_nodes: int, edges: List[List[int]]) -> bool:

# Uses path compression to flatten the structure for faster future lookups.

parent[node] = find\_root(parent[node]) # Path compression

# Initialize the parent list where each node is initially its own parent.

# If the roots are the same, it means we encountered a cycle.

# A tree should have exactly one more node than it has edges.

# After union operations, we should have exactly one component left.

// Method to find the root (using path compression) of the set to which x belongs

// Initialize every node to be its own parent, forming n disjoint sets

// If they do, a cycle is detected and it's not a valid tree

// If x is not the parent of itself, recursively find the root parent and apply path compression

# Union the sets - attach the root of one component to the other.

# Each time we connect two components, reduce the total number of components by one.

# Helper function to find the root of a node 'x'.

We begin by initializing the parent array p with p = [0, 1, 2, 3].

 We iterate through each edge [a, b] in the given edges list: • The first edge is [0, 1]. We find the roots of 0 and 1, which are 0 and 1, respectively. Since they have different roots, we

• The next edge is [1, 2]. The roots of 1 and 2 are 0 and 2. They have different roots, so we union them by setting p[2] to the

• The final edge is [2, 3]. The roots of 2 and 3 are 0 and 3. Again, different roots allow us to union them, updating p[3] to 0.

• After iterating over all the edges, we now check if n equals 1. Since that's the case in our example, it means that all nodes are

connected in a single component, and since we didn't encounter any cycles during the union operations, the graph forms a valid

# tree.

39

**Time Complexity:** 

The given Python code implements a union-find algorithm to determine if an undirected graph forms a valid tree. It uses path

# Each edge leads to a single call to the find function during processing, and possibly a union operation if the vertices belong to different components. Thus, with m edges, there would be 2m calls to find, taking $O(\alpha(n))$ each.

**Space Complexity:** 

Also, the loop through the edges happens exactly m times, where m is the number of edges.

Bringing it all together, the overall time complexity is  $O(m\alpha(n))$ . However, since the graph must have exactly n - 1 edges to form a tree (where n is the number of nodes), m can be replaced by n - 1.

• The find function has a time complexity of  $O(\alpha(n))$  per call, where  $\alpha(n)$  represents the Inverse Ackermann function which grows

Therefore, the time complexity simplifies to  $O((n - 1)\alpha(n))$  which is also written as  $O(n\alpha(n))$ , since the -1 is negligible compared to n for large n.

The time complexity of the validTree function mainly depends on the two operations: find and union.

very slowly. In practical scenarios,  $\alpha(n)$  is less than 5 for all reasonable values of n.

// Union operation: connect the components by making them share the same root parent

parent[findRootParent(nodeA)] = findRootParent(nodeB);

// Decrement the number of components by 1 for each successful union

// A valid tree must have exactly one connected component with no cycles

console.log(validTree(5, [[0, 1], [1, 2], [2, 3], [1, 4]])); // Outputs: true

The space complexity is determined by the storage required for the parent array p, which has length n. The space taken by the parent array is O(n).

- Aside from the parent array p and the input edges, only a fixed amount of space is used for variables like a, b, and x.

Thus, the space complexity of the algorithm is O(n).
