1387. Sort Integers by The Power Value

Memoization Dynamic Programming Sorting

# **Problem Description**

Medium

through a series of steps. These steps consist of halving x if it is even, or replacing x with 3 \* x + 1 if it is odd. The "power" of an integer x is defined as the number of these steps required to reduce x to 1. Given three integers lo, hi, and k, the goal is to find the kth smallest integer in the range [lo, hi] when all the integers within this range are sorted by their power values first (ascending), and by their natural values next (also ascending) if they have the

In this problem, we are introduced to a special mathematical transformation of an integer x, which ultimately reduces x to 1

same power value. Consider an example where lo = 3, hi = 5, and k = 2. Power values for integers 3, 4 and 5 are 7, 2, and 5 respectively. After sorting them by their power values, we get the sequence 4, 5, 3. The second integer in this sequence is 5, which would be the output for these input values.

that x will eventually transform to 1 through the given steps. Intuition

It's guaranteed in this problem that the power value for any integer x within the range will fit within a 32-bit signed integer, and

To solve this problem, we need a function that computes the power of any given number x. The provided solution encapsulates

prevents repeated computation and improves efficiency if the same number appears multiple times during the sorting process. Once we have the function to compute the power of an integer, we can generate all integers within the range [lo, hi] and sort them primarily by the computed power values and secondarily by their natural values in case of ties in power values. This is

achieved by passing the custom sorting key f to Python's built-in sorted function. After sorting, we simply return the k-1 indexed

this in a function f(x), which is decorated with <u>@cache</u> to store the results of computation for each unique value of x. This

element from this sorted list (since lists are zero-indexed in Python). The solution is quite straightforward: 1. Compute the power for each number in the range using the f(x) function. 2. Cache the result each time it's computed to improve efficiency for repeated calculations. 3. Sort all numbers by their power values, and if there's a tie, by their natural values.

The implementation of the solution breaks down into the creation of a helper function f(x) and using built-in Python features to

sort and retrieve the desired kth element.

First, let's discuss the helper function f(x):

4. Return the kth number in the sorted sequence.

# **Helper Function f(x)**

Solution Approach

counter (ans) that tracks the number of steps taken to reduce x to 1. Inside a while loop, as long as x is not 1, the function checks if x is even or odd. If it's even, x is divided by 2, otherwise it's replaced with 3 \* x + 1, as described in the problem. The counter

result of the power calculation for each unique input x. Later calls to the f(x) function with the same x value fetch the result from

The Solution class has a method getKth(lo, hi, k) which leverages the f(x) function to accomplish the task. Here is the step

Use the sorted function to sort this range, passing f as the key argument. By doing this, Python will call f(x) on each element

The sorted function has a time complexity of O(n log n), where n represents the length of the list being sorted. Given that the

the cache rather than recomputing it, significantly saving time especially for ranges with repeated power sequences.

Generate a list of integers from lo to hi, inclusive. This list represents all the candidates for sorting.

function defaults to sorting by the numbers themselves, maintaining them in ascending order.

The helper function f(x) computes the power of a number x according to the rules given in the problem statement. It initiates a

is incremented after each operation. A key optimization implemented here is the use of the <a href="mailto:occupation">occupation</a>. This decorator from the <a href="mailto:functools">functools</a> module caches the

### by step approach:

**Sort and Retrieve kth Element** 

requiring distinct power calculations.

the range and sort them accordingly.

• The power of 8: 8 → 4 → 2 → 1 (total 3 steps).

total is 12 + 5 = 17 steps.

First, we need to compute the power for each integer:

Power values in ascending order: 3 (8), 6 (8), 10 (6), 7 (17), 9 (20).

• Since 3 and 6 have the same power value (8), they will be sub-sorted by their natural values.

cache is in place, each power computation (beyond the first instance) takes O(1) time thanks to the memoization. Once the list is sorted, we are interested in the kth value of this sorted sequence. We simply index into the sorted list with k -1 (to account for 0-based indexing) and return this value.

The final returned value is the kth smallest element by power value, and by numerical order in case of identical powers.

The algorithm's main time complexity is driven by the sorting step which is O(n log n). The space complexity includes O(n) for the

of the range and sort the numbers according to the values returned by f(x). In case of a tie in power values, the sorted

**Example Walkthrough** 

Let's walk through a small example to illustrate the solution approach. Suppose we are given the input lo = 6, hi = 10, and k =

3. We aim to find the 3rd smallest integer by power value in the range [6, 10]. We will calculate the power for each integer within

list of integers and the additional space required by the cache, which at most will be O(n) for a range of different numbers

• The power of 6:  $6 \rightarrow 3 \rightarrow 10 \rightarrow 5 \rightarrow 16 \rightarrow 8 \rightarrow 4 \rightarrow 2 \rightarrow 1$  (total 8 steps). • The power of 7:  $7 \rightarrow 22 \rightarrow 11 \rightarrow 34 \rightarrow 17 \rightarrow 52 \rightarrow 26 \rightarrow 13 \rightarrow 40 \rightarrow 20 \rightarrow 10 \rightarrow 5 \rightarrow ...$  (we have already calculated this from 5: 5 steps). Hence, the

• The power of 9: 9 → 28 → 14 → 7 → ... (we have already calculated this from 7: 17 steps). So the total is 3 + 17 = 20 steps.

integer at index 2 in the sorted list (keeping in mind 0-based indexing). Therefore, the answer is 10.

Generate the list of integers from lo to hi inclusive, which in our case is [6, 7, 8, 9, 10].

• The power of 10: 10 → 5 → ... (we have already calculated from 5: 5 steps). Hence, the total is 1 + 5 = 6 steps. Next, we sort these integers by their power values:

So the sorted list by power and natural values is: 6, 8, 10, 7, 9. We want the 3rd smallest integer by power value, which is the

Create the helper function f(x) with the @cache decorator to calculate power values and make subsequent calculations faster

#### Use Python's sorted function with f as the key argument to sort the integers by their power values and by their natural values if there are ties.

defined criteria. Our final result is the integer 10.

We achieved this using the following steps:

by using cached results.

Solution Implementation

from functools import lru\_cache

def compute\_steps(x: int) -> int:

# Loop until x becomes 1

Time and Space Complexity
  The time complexity and space complexity of the method getKth in the Solution class can be understood in parts.
  Firstly, the function f is decorated with @cache, which uses memoization to store the results of inputs to avoid redundant
  calculations. The complexity of function f without memoization is tough to quantify precisely, as it requires understanding the
  behavior of the Collatz sequence, which is a longstanding unsolved problem in mathematics. Nevertheless, each call to the
```

// Define a helper function to calculate the power value for a given integer.

x >>= 1; // If x is even, right shift to divide by 2.

x = x \* 3 + 1; // If x is odd, multiply by 3 and then add 1.

// If two integers have the same power value, then sort them by numerical value.

function getKth(lo: number, hi: number, k: number): number {

const powerA = calculatePowerValue(a);

const powerB = calculatePowerValue(b);

// Create an array of all integers from lo to hi, inclusive.

# Decorator to cache the results of the function to avoid recalculation

// Function to get the k-th integer in the range [lo, hi] after sorting by their power value.

const nums: number[] = new Array(hi - lo + 1).fill(0).map((\_, index) => lo + index);

// If two integers have the same power value, they will be sorted numerically instead.

return a - b; // Sort by numerical value if power values are equal.

// Sort the array based on the power value calculated via the helper function.

// The power value is the number of steps to transform the integer to 1 using the following process:

## uncached function f performs a series of operations proportional to the length of the sequence required to reach 1, starting from x. During this sequence, the "halving" operation (x //= 2) may occur $0(\log x)$ times, while the "tripling plus one" operation (x = 3)

results would be reused. The method getKth sorts the range [lo, hi], inclusive. Let n = hi - lo + 1 be the number of elements in this range. The sorted function applies the f function as a key, and because of the caching of f, each unique call is 0(log x). However, because we are sorting n elements, the sorting operation has a time complexity of O(n log n). Since each element requires calling function f, and assuming f costs  $0(\log hi)$  at most given its upper bound, the overall time complexity is  $0(n \log n * \log hi)$ . The space complexity primarily comes from two sources: the memoization cache and the sorted list. The cache's size is

\* x + 1) is more unpredictable. Despite this, for our complexity analysis, we can assume a worst-case scenario where these

operations would result in a complexity of O(log x) on average per function call due to memoization, as previously computed

unbounded and depends on the range of numbers and the length of the Collatz sequences encountered—it can potentially reach

0(hi) in space due to the range of unique values passed to f. However, if many values share similar Collatz paths, which is quite

possible, the actual memory usage may be significantly less. The sorted list has a space complexity of O(n). Thus, the overall space complexity may be approximated as O(hi) given the potentially large cache size. In summary: • Time Complexity: O(n log n \* log hi)

• Space Complexity: 0(hi)
