108. Convert Sorted Array to Binary Search Tree Divide and Conquer Binary Tree Binary Search Tree Tree Array Easy

### Leetcode Link

## Problem Description The problem gives us an integer array called nums which is sorted in ascending order. Our task is to convert this sorted array into a

height-balanced binary search tree (BST). A height-balanced binary tree is defined as a binary tree in which the depth of the two subtrees of every node never differs by more than one. Intuition

The solution to the problem lies in the properties of a binary search tree and the characteristics of a sorted array. A binary search tree is a node-based binary tree where each node has the following properties: The left subtree of a node contains only nodes with keys less than the node's key.

- The left and right subtrees must also be binary search trees.
- The challenge is to ensure that the BST is height-balanced. To achieve this, we need to pick the middle element from the sorted

The right subtree of a node contains only nodes with keys greater than the node's key.

array and make it a root, so that the elements to the left, which are lesser, form the left subtree, and the elements to the right, which are greater, form the right subtree.

To construct the BST, we apply a recursive strategy: Find the middle element of the current segment of the array. 2. Make this element the root of the current subtree.

4. Recursively perform the same action on the right half of the array to create the right subtree.

- This divide and conquer approach will ensure that the tree remains height-balanced, as each subtree is constructed from segments of the array that are roughly half the size of the original segment.

a binary search tree as well as being height-balanced.

right subtrees as its children is returned.

to 2. Hence, the middle element is nums [2], which is 0.

3. We create a TreeNode with a value of 0. This is the root of our BST.

By carefully selecting the middle element of the array as the root for each recursive step, the resulting tree satisfies the conditions of

3. Recursively perform the same action on the left half of the array to create the left subtree.

To implement the solution using the given Python code, the following steps are taken, which relate to the concepts of depth-first search (DFS) and recursion:

1. A recursive helper function called dfs is defined, which takes two parameters, 1 and r, which represent the left and right bounds of the segment of the nums array that we are currently considering. This function is responsible for creating nodes in the BST.

### 2. The base case for the recursive function is checked: if 1 > r, it means we have considered all elements in this segment, and there is nothing to create a node with. Therefore, None is returned, indicating the absence of a subtree.

2.

Solution Approach

3. The middle index of the current segment is found using the expression (1 + r) >> 1, which is equivalent to finding the average of 1 and r and then taking the floor of the result. The bitwise right shift operator >>> is used here to efficiently divide the sum by

- 4. The middle element of nums, located at index mid, is the value of the root node for the current segment of the array. A TreeNode is created with this value.
- 5. To build a binary search tree, we need to recursively build the left and right subtrees. The recursive dfs call for the left subtree uses the bounds 1 to mid - 1, while the recursive dfs call for the right subtree uses the bounds mid + 1 to r.

6. After the left and right subtrees are created via recursion, a new TreeNode with nums [mid] as its value and the created left and

the input array nums as the bounds for the entire tree. This approach efficiently builds the binary search tree by always dividing the array into two halves, ensuring the tree is balanced.

The tree's properties as a binary search tree are maintained because we construct the left and right subtrees from elements that are

The choice of using a recursive function encapsulates the logic for both creating TreeNode instances and ensuring that we honor the

7. The outer function sortedArrayToBST initializes the construction process by calling dfs(0, len(nums) - 1) with the full range of

bounds of the current array segment at each step, simplifying the complexity of the task at each recursive call. Example Walkthrough

Using the steps outlined in the solution approach, we would construct a height-balanced BST as follows: 1. We first call the dfs function with the initial bounds set to 1 = 0 and r = 4 (assuming zero-based array indexing).

2. We find the middle element of nums between indices 0 and 4. The midpoint calculation would be (0 + 4) >> 1, which simplifies

4. Now we need to build the left subtree. We make a recursive dfs call with the new bounds, 1 = 0 and r = 1 (mid - 1), focusing

For this subarray, we take the middle element as the root for the left subtree. The midpoint is (0 + 1) >> 1, simplifying to 0.

### on the subarray [-10, -3].

right subtree of 0.

binary search tree property.

# Definition for a binary tree node.

def sortedArrayToBST(self, nums):

self.value = value

self.right = right

self.left = left

nums : List[int]

Args:

left\_index : int

right\_index : int

if left\_index > right\_index:

\* @param right The ending index of the subarray

\* @return The root of the BST subtree constructed from subarray

TreeNode leftSubtree = constructBSTRecursive(left, mid - 1);

TreeNode rightSubtree = constructBSTRecursive(mid + 1, right);

// Base case: If left > right, the subarray is empty and should return null

// Find the middle element to maintain BST properties. Use `left + (right - left) / 2`

private TreeNode constructBSTRecursive(int left, int right) {

middle\_index = (left\_index + right\_index) // 2

# Recursively constructing the left subtree.

return None

def \_\_init\_\_(self, value=0, left=None, right=None):

subtrees of every node never differ by more than one.

class TreeNode:

class Solution:

Args:

1 nums = [-10, -3, 0, 5, 9]

The element at that index in nums is -10, so we create a TreeNode with value -10. • For the left child of -10, the dfs call with l = 0 and r = -1 returns None since l > r.

subarray is 1 and the element at that index is -3, so -3 becomes the right child node of -10.

• The left child of 5 would be None since a recursive call with bounds 1 = 3 and r = 2 returns None.

strictly less than or greater than the root of any subtree, thus satisfying all the properties of the BST.

Let's use a small example to illustrate the solution approach. We are given the following sorted array:

5. Returning to our root 0, we build the right subtree with a new dfs call using the bounds  $l = 3 \pmod{+1}$  and r = 4, focusing on the subarray [5, 9].

The midpoint here is (3 + 4) >> 1, which is 3. The element at index 3 in nums is 5. So, 5 becomes the left child node of the

 $\circ$  For the right child, we have nums [mid + 1] where mid is 0. We make a recursive call with l = 1 and r = 1. mid for this

 For the right child, the new midpoint is 4 (mid + 1 where mid = 3), leading to the element 9 being selected. Hence, 9 is the right child node of 5.

6. At this point, we have successfully constructed all parts of the BST, which would look like this:

Converts a sorted array into a height-balanced binary search tree (BST).

The starting index of the subarray to be processed.

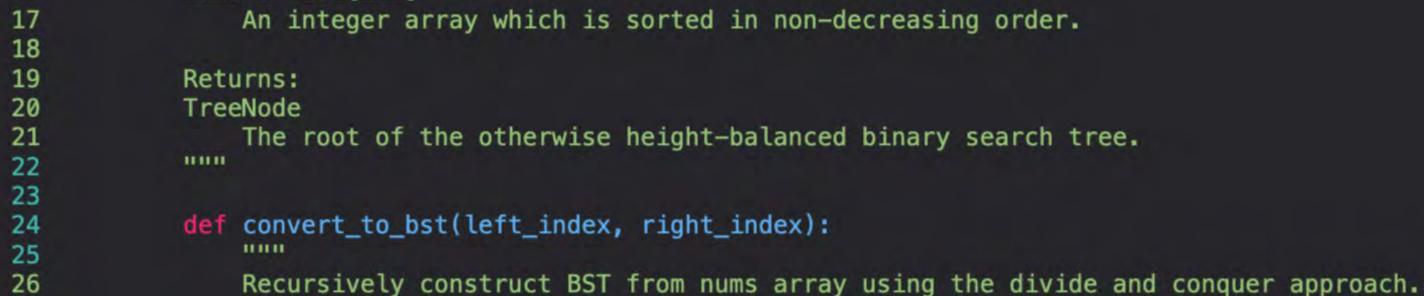

# Choosing the middle element of the subarray to be the root of the BST.

A height-balanced binary tree is a binary tree in which the depth of the two

By following these steps, we have successfully transformed the sorted array nums into a height-balanced BST. The recursive process

ensures that each subtree is constructed from the middle of the subarray it refers to, making the tree balanced and maintaining the
