363. Max Sum of Rectangle No Larger Than K Matrix **Binary Search** Ordered Set **Prefix Sum** Hard Array

Problem Description

within the matrix, where the sum must not exceed k. A rectangle in a matrix is defined by any contiguous block forming an area within the grid. The sum of a rectangle is simply the sum of all the elements it contains. We have the guarantee that there exists at least one such rectangle whose sum is no more than k.

Given a 2D grid called matrix, with dimensions m x n, and an integer k, the problem asks to find the maximum sum of any rectangle

Intuition The significant complexity in solving this problem lies in dealing with two dimensions while trying to optimize for the sum condition. A common approach to problems involving subarray sums is to use a running total and consider differences of this cumulative sum to find subarrays that match certain criteria; however, that typically applies to one-dimensional arrays.

one dimension. We do this by selecting two rows at a time and then compressing those rows into a one-dimensional array where each element is the sum of the elements in the column between the two rows. This effectively converts the problem into the "Maximum Sum of Subarray No More Than K" for a one-dimensional array. Once we have this one-dimensional array, we can use a cumulative sum array to store previous sums and a sorted set to efficiently

When extending this idea to two dimensions, one efficient method is to reduce the problem to a one-dimensional problem by fixing

check if there's a previous sum that, when subtracted from the current sum, gives a result that is as close to k as possible but not greater. The SortedSet in Python comes in handy because it maintains the elements in sorted order, allowing binary-search-like operations for finding the appropriate sums we're interested in. This is a classic case of using space to gain time: we're collecting

possible sums in the sorted set at the expense of memory in order to save significant time on searching. The used algorithm iterates over all possible pairs of rows, for each pair compresses them into a one-dimensional array, computes a running total for that array, and searches the sorted set to find the best match for the current running total that does not exceed k.

until all pairs of rows have been considered, and the overall maximum sum that does not exceed k is the solution to the problem. **Solution Approach** The solution uses a few techniques and data structures. Let's walk through the steps and the rationale behind them:

1. Two-pointer Technique: We iterate over all possible row pairs using two pointers: the outer loop variable i starting from the first

row and the inner loop variable j ranging from i to the last row. This generates all combinations of row starts and ends for our

matrix. We maintain a one-dimensional array nums, where nums [h] represents the sum of elements from row i to j in column h.

2. Cumulative Column Sums: For each row pair (i, j), we compute the cumulative sum for each column in this section of the

The maximum of these matches is remembered as it represents the maximum sum rectangle for the chosen rows. This is repeated

This collapses our two-dimensional problem into a one-dimensional array problem.

larger than k.

smallest number larger or equal to s - k.

(binary search) in the sorted set for each one.

Example Walkthrough

Step 1: Two-pointer Technique

Step 2: Cumulative Column Sums

Step 3: Prefix Sum and Sorted Set

[0, -2, 3],

[1, 2, -1]

rectangles.

3. Prefix Sum and Sorted Set: We create a variable s representing the cumulative sum as we iterate through nums and a SortedSet

ts to store past cumulative sums. The sorted set allows us to effectively perform two crucial operations: adding a new cumulative sum and searching for a particular sum. We start with a zero in the set because that represents an empty rectangle, which conceptually aligns with having no rectangle at all (a sum of zero).

4. Finding the Best Subarray Sum: As we get the cumulative sum s, we're interested in finding some previous sum in our set ts

such that the difference s - previous_sum is as close to k as possible without going over. To do this, we look for the smallest

prefix sum in the set where the s - prefix_sum is still larger than k. We find this prefix using the function ts.bisect_left(s -

k), which does a binary search for the position where s - k could be inserted while maintaining order. This position points to the

5. Maximizing the Subarray Sum: After finding such a prefix sum (ts[p]), we check if the difference s - ts[p] is larger than our previously recorded answer but still not larger than k and update our answer ans accordingly. This process repeats until all row combinations have been exhausted and the ans variable holds the maximum rectangle sum no

The algorithm runs in $O(m^2 * n * log(n))$ time, where m is the number of rows and n is the number of columns. This complexity

comes from the fact that there are $O(m^2)$ row pairs, for each of which we go through n columns and perform a log(n) operation

Let's walk through the solution using a small example. Suppose we have the following 3x3 matrix and k = 8: 1 matrix = [[1, 0, 1],

We'll consider all possible pairs of rows in the matrix. For simplicity, let's look at the pair where the first row has index i = 0 and the second row has index j = 2. This will cover the entire height of the matrix.

Our goal is to find the maximum sum of any rectangle in this matrix that does not exceed k.

We combine rows 0 to 2 into a single one-dimensional array, summing them column-wise:

We set s = 0 and start with an empty SortedSet $ts = \{0\}$ to store cumulatively the sums.

(matrix[0][0] + matrix[1][0] + matrix[2][0]), // First column sum (matrix[0][1] + matrix[1][1] + matrix[2][1]), // Second column sum (matrix[0][2] + matrix[1][2] + matrix[2][2]) // Third column sum

1 nums = [

Step 4: Finding the Best Subarray Sum As we go through the array nums, we add the element to s and search for the best subarray sum:

• For the first column, s = 1, we look for the smallest number in {0} such that when subtracted from s doesn't exceed k. The best

```
• Then for the second column, s becomes 1. There is no change since nums [1] is 0, so the potential sums are identical to the
 previous step.
• Next, for the third column, s becomes 1 + 3 = 4. We look for the smallest number in {0, 1} such that 4 - num is as close as
 possible to k without going over. In both cases, we are under k.
```

a more significant role in efficiently finding the possible rectangle sums.

def max_sum_submatrix(self, matrix, k):

for starting_row in range(num_rows):

A list to store row sums

row_sums = [0] * num_cols

Number of rows and columns in the matrix

num_rows, num_cols = len(matrix), len(matrix[0])

Iterate over the starting row of our submatrix

for col in range(num_cols):

for sum_value in row_sums:

current_sum += sum_value

int maxSumSubmatrix(vector<vector<int>>& matrix, int k) {

vector<int> columnSums(colCount, 0);

set<int> accumulatedSums;

accumulatedSums.insert(0);

for (int sum : columnSums) {

currSum += sum;

// Iterate through each column sum

int currSum = 0;

type Compare<T> = (lhs: T, rhs: T) => number;

// Get the number of rows and columns in the matrix

int rowCount = matrix.size(), colCount = matrix[0].size();

// Outer loop — Start of the row to consider for submatrices

// Inner loop - End of the row to consider for submatrices

for (int rowEnd = rowStart; rowEnd < rowCount; ++rowEnd) {</pre>

// Start with zero as an accumulated sum to compare

auto it = accumulatedSums.lower_bound(currSum - k);

maxSum = max(maxSum, currSum - *it);

// Return the maximum submatrix sum such that it does not exceed k

// If such a number is found, update maxSum if necessary

// Add the current sum to the set of accumulated sums

columnSums[col] += matrix[rowEnd][col];

// Initialize the sum for the current submatrix

if (it != accumulatedSums.end()) {

accumulatedSums.insert(currSum);

1 // Defines a comparator type that compares two items and returns a number.

// Represents a node in a red-black tree with added functionality.

// Sum up the column elements in the current submatrix

for (int rowStart = 0; rowStart < rowCount; ++rowStart) {</pre>

for (int col = 0; col < colCount; ++col) {</pre>

const int INF = INT_MIN; // INT_MIN is from climits and more standard than 1 << 30</pre>

// Initialize an array to store the sum of elements in current submatrix columns

// Use a set to help us find the rectangle with max sum not exceed k

// Find the smallest number in accumulatedSums such that: number >= currSum - k

// Initialize the answer with the smallest integer value

Iterate over the ending row of our submatrix

for ending_row in range(starting_row, num_rows):

row_sums[col] += matrix[ending_row][col]

Iterating over the cumulative sum of row elements

if index != len(sorted_prefix_sums):

sorted_prefix_sums.add(current_sum)

Return the maximum sum found that is less than or equal to 'k'

Find the index of the smallest prefix sum so that

Add the current prefix sum to the sorted set

index = sorted_prefix_sums.bisect_left(current_sum - k)

If such index exists in the sorted set, update the max_sum

7 nums = [1, 0, 3] // Columns summed between rows 0 and 2

we can do is s - 0 = 1 which is less than 8 (our k).

Now, we add s to our sorted set: ts = {0, 1}.

each time to consider it for future subarrays.

Step 5: Maximizing the Subarray Sum

under or equal to k is 4.

Python Solution

sum that does not exceed k is 4, which comes from the sub-matrix: 2 [0, -2, 3]3 [1, 2, -1]

With every addition to s, we continue checking the sorted set ts for the best possible subarray sum, remembering to add s to ts

We continue the above process until all column sums for the current row pair are considered. The largest sum we can achieve

without exceeding k is the one we aim for. In our small example, considering all the combinations, the maximum sum we should find

By repeating Steps 1 to 5 for all row pairs (i, j), we exhaust all possible rectangles in the matrix, and ans is updated each time we

find a larger sum that is within our constraint of k. In this case, after considering all possible rectangles, we find that the maximum

from sortedcontainers import SortedSet from math import inf class Solution:

This variable will store the maximum sum of the submatrix that doesn't exceed 'k'

Update the row sums by adding corresponding values from the new row

current_sum - prefix_sum <= k and we get the biggest current_sum possible

max_sum = max(max_sum, current_sum - sorted_prefix_sums[index])

This is just a simple example that demonstrates the method; in a larger matrix with more variable elements, the sorted set would play

21 22 # Initialize current sum and create a sorted set to store prefix sums 23 current_sum = 0 24 sorted_prefix_sums = SortedSet([0]) 25

return max_sum

There are two nested loops (loop over i and j) that iterate over the rows of the matrix. In the worst case, both loops iterate m times, where m is the number of rows. This part contributes $O(m^2)$ to the time complexity. Inside the nested loops, there's another loop over h that iterates n times where n is the number of columns, to sum up the

Time and Space Complexity

analysis of its time and space complexity:

factor. • For each nums subarray created, we perform a binary search and insertion into a sorted set ts. The SortedSet operations are logarithmic with respect to the size of the set. The set could potentially contain up to n elements in the worst case, so each

elements in the current rectangle (nums). This loop runs n times for each iteration of the outer two loops, adding an $0(m^2 * n)$

The given code implements an algorithm to find the maximum sum of a submatrix in a 2D array that is no larger than k. Here's the

- operation (bisect_left and add) will take O(log n). As these sorted set operations are done for each element in nums, this
- results in an additional O(n log n) term. • Combining the factors, the overall time complexity is $0(m^2 * n * n * \log n) = 0(m^2 * n^2 * \log n)$.

94 // ...

Time Complexity

Space Complexity The space complexity is mainly determined by the space needed to store the nums array and the sorted set ts.

As these are the largest allocations and no other allocations grow with respect to m or n, the total space complexity is O(n).

In conclusion, the time complexity of the code is $0(m^2 * n^2 * \log n)$ and the space complexity is 0(n).

• The sorted set ts can contain up to n prefix sums, contributing another O(n) to the space complexity.

• The array nums has a size of n, so it contributes O(n) to the space complexity.

// Define additional methods and variables here that are necessary for the global implementation.
