416. Partition Equal Subset Sum

Dynamic Programming Medium Array

Problem Description

The given problem asks us to determine if we can split an array of integers, nums, into two subsets such that the sum of the elements in both subsets is the same. This is essentially asking if nums can be partitioned into two subsets of equal sum. If such a partition is possible, we should return true, otherwise, we return false.

To understand this problem better, imagine you have a set of blocks with different weights, and you want to see if you can divide them into two groups that weigh the same. If it can be done, then each group represents a subset with an equal sum.

Intuition

The solution to this problem is based on the concept of <u>dynamic programming</u>, particularly the 0/1 Knapsack problem, where we

The intuition behind this solution is:

First, we calculate the sum of all elements in the array. If the sum is an odd number, it's impossible to partition the array into

one (m + 1), with the first value True (since we can always reach a sum of 0) and the rest False.

0/1 Knapsack problem. Here's a step-by-step guide to understanding the algorithm:

aim to find a subset of numbers that can sum up to a specific target, in this case, half the sum of all elements in nums.

two subsets with an equal sum, so we immediately return false. If the sum is even, our target becomes half of the total sum, and we set up an array f of boolean values that represents if this

sum can be reached using a combination of the numbers we've seen so far. f is initialized with a size equal to the target plus

- We iterate over each number in our array nums. For each number, we update our f array from right to left, starting at our target m and going down to the value of the number x. We do this backward to ensure that each number is only considered once. At each position j, we update f[j] by checking if f[j] was previously true or if f[j-x] was true. The latter means that if we
- already could sum up to j-x, then by adding x, we can now also sum up to j. At the end of this process, f[m] tells us whether we've found a subset of elements that sum up to m, which would be half the sum of the entire array. If f[m] is true, we have our partition and return true, otherwise, we return false.
- Solution Approach The solution implements a classic <u>dynamic programming</u> approach to solve the subset sum problem, which is a variation of the

Calculate the Sum and Determine Feasibility: We begin by finding the sum of all elements in the array using sum(nums). We

divide this sum by 2 using the divmod function, which gives us the quotient m and the remainder mod. If mod is not zero, the sum is odd, and we cannot partition an odd sum into two equal even halves, so we return false.

<u>Dynamic Programming</u> Array Setup: Next, we set up an array f with m + 1 boolean elements, which will help us track which

sums can be achieved from subsets of the array. We initialize f[0] to True because a zero sum is always possible (the empty

Update the DP Array: For each position j in f, we check if f[j] was already True (sum j was already achievable) or if f[j -

x] was True. If f[j - x] was True, it means there was a subset of previous elements that added up to j - x. By including the

- subset), and the rest to False. **Iterate and Update the DP Array:** For each number x in nums, we iterate over the array f from m down to x. We do this in reverse order to ensure that each element contributes only once to each sum.
- current element x, we can now reach the sum j, so we set f[j] to True. **Return the Result:** Finally, we return the value of f[m]. This value tells us whether there is a subset of elements from nums that
- adds up to m, which would be half of the total sum. If f[m] is True, it means we can partition the array into two subsets with an equal sum, and we return true; otherwise, we return false. The pattern used in this algorithm leverages the properties of boolean arithmetic wherein True represents 1 and False represents

0. The statement f[j] = f[j] or f[j - x] is an efficient way to update our boolean array because it captures both conditions

for setting f[j] to True: either it's already True, or f[j - x] is True and we just add x to reach the required sum j.

which is much more efficient than trying to store all possible subset sums up to the total sum of the array. **Example Walkthrough**

Let's walk through an example to illustrate the solution approach. Consider an array nums with the following elements: [1, 5, 11,

By re-using the array f in each iteration and only considering each number once, we keep our space complexity to O(sum/2),

5]. Calculate the Sum and Determine Feasibility:

Since the remainder is 0, the sum is even, and proceeding is feasible.

Dynamic Programming Array Setup:

 For x = 1 (first element), update f from 11 down to 1. Since f[0] is True, set f[1] to True. \circ For x = 5 (second element), update f from 11 down to 5. Now f[5], f[6], f[7], f[8], f[9], and f[11] become True.

Update the DP Array:

Solution Implementation

Python

class Solution:

Iterate and Update the DP Array:

Our target sum m is 22 / 2 = 11.

Return the Result:

Start iterating over the array nums: [1, 5, 11, 5].

 \circ Compute the sum of the elements: 1 + 5 + 11 + 5 = 22.

Initialize f with dimensions [12] (m + 1) and set f[0] to True.

Use divmod to check if the sum is even or odd: divmod(22, 2) gives us (11, 0).

 \circ Lastly, for x = 5 (fourth element), update f again similarly to when x was 5 before.

This indicates that there is a subset with a sum of 11, which is half of the total sum.

Initialize a boolean array that will keep track of possible sums

True if the number itself can form the sum

can_partition[j] = can_partition[j] or can_partition[j - num]

The last element in the can_partition array indicates if we can partition

// The result is whether the targetSum is achievable as a subset sum

// Function to determine if the input array can be partitioned into two subsets of equal sum

// If the total sum is odd, it's not possible to divide it into two equal parts

// Create a dynamic programming array to keep track of possible sums

After the final iteration, we check the value of f[11], which is True.

Therefore, the array [1, 5, 11, 5] can be partitioned into two subsets with equal sum, and we return true.

def can_partition(self, nums: List[int]) -> bool:

can_partition = [True] + [False] * total_sum

for j in range(total_sum, num - 1, -1):

Update the can_partition array

Compute the total sum of the nums array and divide by 2 (partition sum) total_sum, remainder = divmod(sum(nums), 2) # If the sum of nums is odd, we cannot partition it into two equal subsets

or if the sum can be formed by adding the number to a previously possible sum

• For x = 11 (third element), since f[0] is True, set f[11] to True. However, f[11] is already True from the previous step.

Loop through each number in the nums array for num in nums: # Check each possible sum in reverse (to avoid using the same number twice)

if remainder:

return False

nums into two equal subsets

return subsetSums[targetSum];

Time Complexity

nums into two equal subsets

Time and Space Complexity

return can_partition[total_sum]

def can_partition(self, nums: List[int]) -> bool:

Compute the total sum of the nums array and divide by 2 (partition sum)

The last element in the can_partition array indicates if we can partition

partitioned into two subsets such that the sum of elements in both subsets is the same.

The time complexity is 0(n * m) where n is the number of elements in nums and m is half the sum of all elements in nums if the sum is even. This complexity arises from the double loop structure: an outer loop iterating over each number x in nums, and an inner loop iterating backwards from m to x. The inner loop runs at most m iterations (representing the possible sums up to half the total sum), and this is done for each of the n numbers.

The code is designed to solve the Partition Equal Subset Sum problem which is to determine if the given set of numbers can be

Space Complexity

The space complexity is 0(m) where m is half the sum of all elements in nums (if the sum is even). This is due to the array f, which stores Boolean values indicating whether a certain sum can be reached with the current subset of numbers. The array f has a length of m + 1, with m being the target sum (the zero is included to represent the empty subset).
