2786. Visit Array Positions to Maximize Score

You are provided with an int array nums that is 0-indexed and a positive int x. The goal is to calculate the maximum total score you can obtain starting at position 0 of the array and moving to any subsequent position. The rules are outlined as follows:

Leetcode Link

When you visit position i, you earn nums[i] points added to your score.

You can move from your current position i to any position j such that i < j.

- If you move between positions i and j and nums[i] and nums[j] have different parities (one is odd, the other is even), you lose x
- points from your score. You kick off with nums [0] points, and you have to figure out the maximum score that can be achieved under these conditions.

Intuition

number.

Here's an outline of the approach:

Problem Description

- Iterate through the nums array starting from index 1. For each value v at index i: Calculate the maximum score when staying on the same parity (f[v & 1] + v) and when changing parity (f[v & 1 ^ 1] + v

2. The last score came from an index with different parity. Here, you add the current value to the previous score from the opposite

parity and subtract the penalty x.

The implementation uses a dynamic programming approach to compute the maximum score. Here's a step-by-step walkthrough:

Firstly, the algorithm initializes a list f with two elements, [-inf, -inf]. This record is to keep track of the two possible states

for our score related to parity: even (0) and odd (1). In Python, -inf denotes negative infinity which is a useful placeholder for

parity.

max function.

1 class Solution:

• f = [4, 9]

Next, nums [2] = 2, which is even:

With nums[3] = 7, which is odd:

• Staying odd, f[1] + 7 = 9 + 7 = 16.

• Staying odd, f[1] + 3 = 16 + 3 = 19.

The maximum score we can get is max(f), which is 19.

def maxScore(self, nums: List[int], x: int) -> int:

and assigned as the initial score for that parity

Update the score for the current parity

max_scores = [-math.inf, -math.inf]

max_scores[nums[0] % 2] = nums[0]

// Method to calculate the maximum score.

public long maxScore(int[] nums, int x) {

long[] maxScoreForOddEven = new long[2];

Arrays.fill(maxScoreForOddEven, -(1L << 60));

// numParity is 0 for even and 1 for odd.

maxScoreForOddEven[numParity] = Math.max(

// Return the maximum score among the two parities.

maxScoreForOddEven[numParity] + nums[i],

maxScoreForOddEven[numParity ^ 1] + nums[i] - x

return Math.max(maxScoreForOddEven[0], maxScoreForOddEven[1]);

// Iterate over the array, starting from the second element.

maxScoreForOddEven[nums[0] & 1] = nums[0];

for (int i = 1; i < nums.length; ++i) {</pre>

int numParity = nums[i] & 1;

for value in nums[1:]:

parity = value % 2

Initialize a list with two elements representing negative infinity

The first number's score is determined based on its parity (even/odd)

Iterate over the remaining numbers starting from the second element

Determine the parity of the current number, 0 if even, 1 if odd

or switching parity and applying the penalty/subtraction of x

max() is choosing the greater value between continuing the same parity

// Array f to store the current maximum score for odd and even indexed numbers.

// Initialize both entries with a very small number to simulate negative infinity.

// The first number decides the initial maximum score for its parity (odd or even).

// Update the maximum score for the current parity (odd or even).

The list is used to track the maximum scores for even and odd numbers separately

f = [-inf] * 2

for v in nums[1:]:

f[nums[0] & 1] = nums[0]

The expression nums [0] & 1 will be 0 if nums [0] is even, and 1 if it is odd, so it determines the index of f that gets updated.

 Staying on the same parity (f[v & 1] + v), ∘ Switching parity (f[v & 1 ^ 1] + v - x). The ^ operator is a bitwise XOR, which flips the bit, effectively getting us the other

The update for the score at parity v & 1 chooses whichever of these two possibilities gives a higher score. This is done by the

return max(f)

```
Example Walkthrough
Let's illustrate the solution approach with a small example:
Suppose we have the array nums = [4, 5, 2, 7, 3] and the penalty x = 3.
We initiate the variable f with two elements [-inf, -inf] to keep track of the max scores for the even (f[0]) and odd indices (f[1]).
```

apply the penalty x. The new score would be 5 - 3 = 2.

def maxScore(self, nums: List[int], x: int) -> int:

 $f[v \& 1] = max(f[v \& 1] + v, f[v \& 1 ^ 1] + v - x)$

through all potential positions and parities, significantly reducing the complexity of the problem.

We move to nums[1] = 5, which is odd:

• If we stay with odd, f[1] would become 5 (since -inf + 5 is just 5), but there's a catch: we start from an even index so we must

• If we switch to even, f[0] + nums[1] would be 4 + 5 = 9. We take the max of both, which is 9, so we update f[1].

```
    Staying with even parity, f[0] + 2 = 4 + 2 = 6.
```

- Switching to even, f[0] + 7 x = 8 + 7 3 = 12. We take the max which is 16 and update f[1]. • f = [8, 16]
- Switching to even, f[0] + 3 x = 8 + 3 3 = 8. The max is 19, so f[1] remains 19. • f = [8, 19]

The entire process demonstrates the dynamic programming algorithm's effectiveness in computing the maximum score by

considering the penalty for switching between even and odd numbers. Each decision is based on whether to continue the sequence

Typescript Solution
   function maxScore(nums: number[], x: number): number {
       // Define a very large number to represent "infinity".
```

list:

const INFINITY = 1 << 30;

 The for-loop runs (n - 1) times, as it starts from the second element in nums. Within the loop, a constant number of operations are executed: two bitwise AND operations, four direct accesses by index to the list f, up to two max operations, and a few arithmetic operations.

Since these operations inside the loop are all of constant time complexity, the overall time complexity of the loop is 0(n-1).

- Simplifying this, we get: 0(n-1)=0(n).
- Thus, the time complexity of the code is O(n).

As for the space complexity:

- A new list f of fixed size 2 is created. This does not depend on the size of the input and is thus 0(1). Variable v is a single integer that is used to iterate through nums, which is also 0(1) space.
- Therefore, the space complexity of the code is 0(1).

Without a reference answer provided alongside the code, the analysis is based solely on the provided snippet.

The task is to maximize the score while taking into account that moving between numbers of different parity comes with a penalty of x points. To do this, we need to use dynamic programming to track the highest scores while considering the parity of the current

 Initialize a list f with two elements, set to negative infinity [-inf, -inf]. This list will keep track of the max scores for even and odd indices. Set the element of f corresponding to the parity of nums [0] (even or odd) to nums [0]. This represents the score starting at position 0.

-x).

 Update f[v & 1] with the highest score from the above step. After processing all elements, the maximum score will be the maximum element from f.

The key intuition in this solution comes from recognizing that at any index 1 in the array, you have two scenarios to consider: 1. The last score came from an index with the same parity as i. In this case, you just add the current value to the previous score since no penalty is incurred.

This process will lead us to the highest possible score, taking into account the penalty for switching parities. Solution Approach

"not yet computed or improbably low score." • The first element of nums is factored into our initial state. Since we always start at position 0, f[nums[0] & 1] is set to nums[0].

scenarios:

The algorithm then iterates through elements in nums starting from index 1. For each value v, it computes the two possible

- After evaluating all elements in nums, the maximum score is the highest value in f, which can be obtained using Python's built-in max(f) function. The code snippet provided succinctly translates this approach into a Python function as part of a Solution class:
- Each iteration effectively represents a choice at every position i with a value v from nums: taking its score as part of the existing parity sequence or starting a new sequence of the opposite parity with an x penalty. The algorithm dynamically keeps track of the

best choice by updating only the score of the relevant parity after each decision. This pattern avoids the need for recursive traversal

- f = [-inf, -inf] Starting at position 0, nums[0] = 4, which is even, so we update f[0] with the value of nums[0]. f = [4, -inf]
- Switching to odd, f[1] + 2 x = 9 + 2 3 = 8. The higher score is 8, so f[0] becomes 8. • f = [8, 9]
- Lastly, nums[4] = 3, which is odd:
- of the current parity or start a new one of the opposite parity with a penalty. The algorithm avoids the need to check each path separately, instead of using a running tally that gets updated in each step, which is considerably more efficient.

class Solution {

// Case when adding the current number to the same parity.

// with the penalty x.

// Case when adding the current number leads to change in parit

```
// Initialize an array 'scores' with two elements representing the max scores for even and odd indices.
       const scores: number[] = Array(2).fill(-INFINITY);
       // For the first number, update the score based on it being even or odd.
       scores[nums[0] & 1] = nums[0];
       // Loop through the numbers starting from the second element.
9
       for (let i = 1; i < nums.length; ++i) {</pre>
10
           const isOdd = nums[i] & 1;
           // Update the score for the current parity (even or odd).
           // The updated score is the max of the current score for the same parity plus the current number,
           // or the score for the other parity plus the current number minus x.
14
           scores[isOdd] = Math.max(scores[isOdd] + nums[i], scores[isOdd ^ 1] + nums[i] - x);
15
16
17
       // Return the maximum score between the even and odd indices.
18
       return Math.max(scores[0], scores[1]);
19
20 }
21
Time and Space Complexity
The given Python code snippet aims to calculate a certain "maximum score" by iterating through the input list nums and applying
some operations based on the elements' parity (odd or even) and a given integer x. To analyze the time and space complexity of this
code, let's consider n to be the length of the input list nums.
Time Complexity
The time complexity of this code is determined by the number of operations performed in the for-loop that iterates through the nums
```

Space Complexity

- There are no other data structures or recursive calls that use additional space that scales with the input size.
