# 1105. Filling Bookcase Shelves

**Problem Description** 

[thicknessi, heighti]. We also have a bookshelf of a fixed width, shelfWidth. The goal is to arrange the books in such a way that they all fit on the shelves while maintaining their original order and minimizing the total height of the bookshelf.

In this problem, we're given an array books where each books [i] represents the ith book with its thickness and height as

The process for placing books onto the bookshelf is as follows:

Books are taken from the array in the same order they are given and placed onto the shelf.

- A group of books can be placed on the same shelf if their total thickness does not exceed the shelf width.
- Once a shelf is filled (or can't fit the next book without exceeding shelfwidth), a new shelf is started above it. The height of each shelf is determined by the tallest book on that shelf.
- The process continues until all books are placed on the shelf. The total height of the bookshelf is the sum of the heights of each individual shelf.
- The challenge is to determine the least total height of the bookshelf after all the books are placed according to the rules.

For the solution, dynamic programming is used to keep track of the optimal height at each step. The key idea is to iteratively

## determine the minimum height required to arrange all books up to the current one. Here's a step-by-step breakdown:

Intuition

2. For each book, calculate the minimum height if this book starts a new shelf by adding its height to the minimum height found for all previous books.

3. Then, for the same book, consider the possibility of placing it on the same shelf as the previous book(s). For each cluster of books that can fit together on the same shelf without exceeding shelfWidth, calculate the minimum height needed if these

1. Initialize a dynamic programming array f of n + 1 elements, where n is the number of books.

- books shared a shelf. 4. To do this, iterate backwards from the current book and keep adding the thicknesses of each previous book until the total
- 5. As you go along, keep track of the maximum height of the books in the current shelf arrangement since that determines the height of the shelf. 6. Update the minimum height for the current set of books as the lesser of the existing minimum height or the height required if
- these books share a shelf, which is the sum of maximum book height on this shelf and the minimum height found before starting this shelf. 7. After calculating for all books, the last element in the f array will contain the minimum possible height of the bookshelf.

The optimization comes from recognizing that the best height for a set of books up to the ith book is either on a new shelf or

combined with some recent books on the same shelf to minimize the height added. By comparing each possibility, we guarantee we're finding the optimal combination at each step.

The solution provided uses dynamic programming as its primary algorithmic strategy. This involves breaking a larger problem down

into smaller subproblems and storing the results of those subproblems to avoid redundant computations. Here's how the algorithm

**Solution Approach** 

the bookshelf when the last book placed is the ith book (f[i]). • We loop through each book, and for each book (w, h):

We then consider the possibility of placing each book in reverse order onto the same shelf, starting by adding the second

combination, we update the current maximum height of the books on the shelf and check if the minimum total height f[i]

Then, we calculate the minimum total height f[i] by comparing its current value with the sum of the maximum shelf height h

and the minimum height f[j - 1] that can be achieved before adding the books currently considered on the shelf. We then

last book and so on, until we either run out of books or the total thickness would exceed the shelfWidth. For each

can be improved by placing the current book on the same shelf as the previous one(s).

Let's illustrate the solution approach with a small example. Suppose we have an array of books:

will store the minimum total height after the ith book has been placed.

# List to store the minimum height at each point

for i, (width, height) in enumerate(books, 1):

total\_width += books[j - 1][0]

public int minHeightShelves(int[][] books, int shelfWidth) {

// Return the minimum height to place all the books

int minHeightShelves(vector<vector<int>>& books, int shelfWidth) {

return dp[numOfBooks];

// Total number of books

int numBooks = books.size();

vector<int> dp(numBooks + 1);

# Initially, put the book on a new shelf

min\_height[i] = min\_height[i - 1] + height

# Initialize the total width of the current shelf

# Try placing previous books on the same shelf and check

# Add the width of the book j to the total width

# if it can minimize the total height of the shelves

 $min_height = [0] * (num_books + 1)$ 

# Loop through each book

total\_width = width

return min\_height[num\_books]

int numOfBooks = books.length;

for j in range(i - 1, 0, -1):

maximum height of the first two books, which is 3. So, f[2] remains 3 since 3 < 4.

Within the inner loop, we are performing the following computations:

• An array f of length n + 1 is initialized with zeroes, where n is the number of books. The array f will hold the minimum height of

∘ We set f[i] to f[i - 1] + h by default, assuming the book (w, h) starts a new shelf, where i is the current book's index in one-based notation. This means we add the height of this book to the total height we had before adding this book.

backwards).

trying to add to the shelf.

select the minimum of those two values.

1 books = [[1, 1], [2, 3], [2, 3], [1, 2]], shelfWidth = 4

works step by step:

thickness exceeds shelfWidth.

• If w exceeds shelfWidth, we break out of the loop as we can't add any more books to the current shelf. Otherwise, we update the current maximum height h to be the maximum of the current h and the height of the book we're

Increment the total thickness w by the thickness of the previous book (starting from the current book and moving

• This loop continues for all books, and once we have considered all possible placements for each book, the last element of f, f[n], holds the minimum total height of the bookshelf, which is the final answer.

The data structure used is a simple array (f), which holds the best solution to subproblems (best bookshelf height given a certain

number of books). By iterating over the possible placements for each book, we are effectively employing a bottom-up dynamic

programming approach. In summary, the algorithm builds upon previous solutions to maintain the minimum height required at each step, while considering new book placements, to achieve an overall optimal arrangement with respect to the total height.

and we want to arrange the books on a bookshelf with a shelf width of 4. We follow the solution approach using dynamic programming.

1. We initialize an array f with length n + 1 where n is the number of books. In our case, n=4, so f = [0, 0, 0, 0, 0]. This array

book) = 1 + 3 = 4, so f[2] = 4. However, since its thickness (2) plus the thickness of the first book (1) does not exceed the

shelfWidth (4), we also check if we can place it on the same shelf as the first book. This would keep the shelf height as the

# 3. Now place the second book [2, 3]. If it starts a new shelf, the minimum total height after this book is f[1] + height(second

**Example Walkthrough** 

4. Now consider the third book [2, 3]. If it starts a new shelf, then the minimum total height is f[2] + height(third book) = 3 + 3 = 6. But can it fit with the second book on the same shelf? The total thickness would be 2(second book) + 2(third book) =

2. Start with the first book [1, 1]. If it starts a new shelf, the total height is just the height of this book, so f[1] = 1.

which is less than shelfWidth, and we find the max height among the first and third books to be 3. So, the minimum height becomes f[3] = 1(original height of the first shelf with only the first book) + 3(height of the third book) = 4. Since 4 < 6, we update f[3] = 4.

5. Finally, the fourth book [1, 2]. Starting a new shelf would result in f[3] + height(fourth book) = 4 + 2 = 6. Can it fit on the

thickness 2(second book) + 2(third book) + 1(fourth book) = 5 exceeds the shelf width. So, it must start a new shelf. As the

fourth book is shorter than the third, it doesn't alter our already calculated f[3]. However, we check if the first and fourth book

can share a shelf, and they can as their combined thickness is 2, and the shelf height will be determined by the fourth book 2.

So, f[4] would be 1(height of the first shelf) + 2(height of the fourth book) = 3. The total minimum height f[4] is 3.

same shelf as the third? No, because 2(third book) + 1(fourth book) = 3, and if we include the second book, the total

4, which is equal to shelfWidth, and the height would be the taller book's height, which is 3, so the total height is still 3 + 3 = 6.

Now, can we fit the first and third books together instead? The total thickness would be 1(first book) + 2(third book) = 3,

So, by following the dynamic programming approach, we've determined that the books can be arranged in the smallest total height which is 3. The arrangement would be: first and fourth book on the bottom shelf and second and third books on the shelf above. Python Solution class Solution: def minHeightShelves(self, books: List[List[int]], shelf\_width: int) -> int: # Number of books num\_books = len(books)

// If width exceeds the shelf width, stop the loop

// Iterate through the previous books to find minimum height for the current shelf

// Initialize the height of the current shelf

Time and Space Complexity The given Python function calculates the minimum height of a shelf that can contain all the books, given a list of book dimensions

The outer loop iterates over each book (n iterations, where n is the number of books). Inside the outer loop, there is an inner loop

that iterates backward from the current book index i to 1. This inner loop runs at most i times, and since it decreases progressively,

### it results in a series that sums up roughly to n(n + 1)/2 in the worst case. The operations within the inner loop are constant-time operations.

Time Complexity:

**Space Complexity:** For space, an array of size n + 1 is used to store the running minimum heights, where n is the number of books. No other space-

consuming structures are used. Thus, the space complexity is linear. Hence, the space complexity is O(n).

Consequently, the overall time complexity is  $0(n^2)$ .
