2448. Minimum Cost to Make Array Equal Binary Search Greedy Array Prefix Sum Sorting Hard

## Leetcode Link

# Problem Description In this problem, we are given two arrays nums and cost of equal length n. The nums array holds the actual values of the elements we

the nums array by 1.

must manipulate, and the cost array indicates how much it costs to increase or decrease an element in the corresponding position of

Our objective is to make all elements in the nums array equal to each other by either increasing or decreasing their values. The catch is, every operation has a cost associated with it, based on the cost array. We want to find the minimum total cost required to achieve this.

The main challenge is to figure out what value we should aim for all elements in the nums array to reach, and do this as cost-efficient as possible. Intuition

The solution hinges on finding a target value in the nums array that minimizes the total cost. Intuitively, aiming for a value too high or

too low will not be cost efficient, as it would require more operations for elements that are far from such extremes.

## In fact, a good target value can be one of the current elements in the nums array, since aiming for a value not present may potentially

better efficiency.

Solution Approach

Sorting the array nums along with cost will help us approach this problem methodically. The sorted nature of nums allows us to consider the pivot elements (target values) one by one and calculate the cost required to make the rest of the elements equal to the

pivot. Here is a step-by-step explanation of how the solution works:

1. We zip and sort nums and cost together based on the nums values. This pairs each element of nums with its corresponding cost. 2. We prepare prefix sums for both nums multiplied by cost (f) and for cost alone (g) which will help us calculate the cost with

r is the total cost to increase the right part of the array to the current target value. 4. The minimum of these calculated costs (ans) for each element being the target is the answer we are seeking. It represents the

lowest possible cost to make all elements in nums equal.

increase the total cost compared to aiming for a value already there.

- 3. We iterate through each possible target value (which are now sorted) and calculate the total cost required for the rest of the array to reach this target value. This is done in two parts: 1 is the total cost to decrease the left part of the array to the current target value.
- The algorithm explores all elements as potential targets and uses cumulative costs to determine the most cost-effective target, hence ensuring we find the minimum total cost to equalize all elements in the given nums array.
- The implementation of the solution can be broken down into several key steps that leverage algorithms and data structures to find the minimum total cost efficiently:

1. Sorting with Zip: The zip function is used to combine nums and cost into a single list of tuples. This list is then sorted based on

the nums values using Python's sorted() function. Sorting is crucial as it allows us to easily calculate the cost of changing every

other element to match a particular element (the pivot). 2. Prefix Sums: Two types of prefix sums (f and g) are utilized.

Example Walkthrough

Following the solution approach:

similar to the left part calculation.

g is the sum of the cost elements up to the current index. It is used to calculate the total cost of changing the left or right part of the array to match the current pivot. 3. Dynamic Calculation of Costs: For each potential target value (a), the total cost is computed in two halves: the cost to adjust

elements to the left (1) and the cost to adjust elements to the right (r) of the current index.

• f represents the sum of elements of nums each multiplied by its corresponding cost up to the current index. This is

calculated as f[i] = f[i - 1] + a \* b, where a is the value in nums and b is the value in cost for the current element.

• The cost to the left is computed as l = a \* g[i - 1] - f[i - 1]. Here, a \* g[i - 1] estimates the total cost if all elements to the left were increased to a, and f[i - 1] subtracts the excess since we've already some elements at the desired value or higher.

• The cost to the right is computed as r = f[n] - f[i] - a \* (g[n] - g[i]). Here, f[n] - f[i] represents the total sum

that would have been without decreasing any elements from nums[i] onwards, and a \* (g[n] - g[i]) subtracts the excess,

lower on the first comparison. As the loop iterates through each pivot, the algorithm computes the total cost for each pivot and updates ans to be the minimum between the current ans and the newly calculated total cost (1 + r).

This approach is efficient because it cleverly reduces what could be many variable operations into a simple range of sums and

differences by leveraging the sorted nature of the array and mathematically sound calculations to find the minimum total cost.

5. Returning the Result: After the loop, the ans value will hold the minimum cost found, and this value is returned as the solution.

4. Finding the Minimum: The variable ans is initialized with the value inf (infinity) to ensure that any real calculated cost will be

- Let's consider a small example to illustrate the solution approach with the following nums and cost arrays: nums = [3, 1, 2, 4] cost = [4, 2, 3, 1]
- 3 \* 4 = 20 f[3] = f[2] + 4 \* 1 = 24For g (cumulative sum of cost), we get: g[0] = 2g[1] = g[0] + 3 = 5g[2] = g[1] + 4 = 9g[3] = g[2] + 1 = 10

2. Prefix Sums: For f (cumulative sum of nums times cost), we compute: f[0] = 1 \* 2 = 2 f[1] = f[0] + 2 \* 3 = 8 f[2] = f[1] + 2 = 2 f[1]

Using 1 as the target, the cost to increase is 0 (since it's already the lowest): 1 = 1 \* g[0] - f[0] = 0 The cost to decrease

elements to the right: r = f[3] - f[1] - 2 \* (g[3] - g[1]) = 24 - 8 - 2 \* (5) = 6 Total cost for target 2 is 1 + r = 2 + 1

4. Finding the Minimum: Initialise ans = inf. After computing 1 + r for all possible targets, we'd find ans is minimum for target 2 at

1. Sorting with Zip: Pairing and sorting based on nums values gives us: sorted\_pair = [(1, 2), (2, 3), (3, 4), (4, 1)]

Using 2 as the target, we compute 1 with elements to the left: 1 = 2 \* g[0] - f[0] = 2 \* 2 - 2 = 2 Compute r for

3. Dynamic Calculation of Costs: We consider each element in nums as the target. For example:

# Combine nums and costs into a list of tuples and sort them by 'nums'

Similarly, we would compute for targets 3 and 4.

make all elements in the nums array equal to 2 is 8.

def min\_cost(self, nums, costs):

n = len(num\_cost\_pairs)

# Prefix sums of costs

# Calculate prefix sums

answer = float('inf')

# Calculate the minimum cost

**Time Complexity** 

return answer;

The time complexity of the given code can be broken down into a few components: 1. Sorting the combined list of nums and cost: This is done using the sorted() function, which typically employs the Timsort algorithm, having a time complexity of  $O(n \log n)$  where n is the length of the list to be sorted.

prefixCostSum[i] = prefixCostSum[i - 1] + number \* cost;

let answer: number = Number.MAX\_SAFE\_INTEGER; // Using maximum safe integer value in JS

// Calculate the cost of making all numbers to the left equal to 'number'

// Calculate the cost of making all numbers to the right equal to 'number'

let leftCost: number = number \* prefixCountSum[i - 1] - prefixCostSum[i - 1];

prefixCountSum[i] = prefixCountSum[i - 1] + cost;

// Calculate the minimal total cost to make all numbers equal

// Update the answer with the minimum cost found so far

answer = Math.min(answer, leftCost + rightCost);

// Initialize answer to a very high value

let [number, \_] = pairedArray[i - 1];

for (let i = 1; i <= n; i++) {

// Return the minimal total cost

Time and Space Complexity

- 2. Populating the f and g arrays: The two arrays are filled by iterating over arr once, which has n elements. The operations within the loop are constant time, making this step take O(n) time.
- 3. Calculating the minimum cost ans: This involves iterating over each element in arr and performing constant time operations, thus taking O(n) time.
- Overall, the time complexity is dominated by the sorting operation. Hence, the total time complexity of the code is 0(n log n). Space Complexity

2. The f and g arrays, each of which has n + 1 elements, thus together taking 2(n + 1) which is equivalent to 0(n) space.

3. The ans variable, which is constant space 0(1).

The arr list, which stores the sorted nums and cost, taking O(n) space.

The space complexity can be attributed to the extra storage used by:

Therefore, the total space complexity of the code is O(n).
