780. Reaching Points

<u>Math</u> Hard

Problem Description

The problem presents an operation that can transform a point (x, y) in a two-dimensional grid to either (x, x + y) or (x + y)y). Given four integers sx, sy, tx, and ty, which represent the starting point (sx, sy) and the target point (tx, ty), the task is to determine if it is possible to reach the target point from the starting point by repeatedly applying the transformation.

1. Add the current y value to the x value, changing (x, y) to (x + y, y).

The only allowed operations are:

```
2. Add the current x value to the y value, changing (x, y) to (x, x + y).
The key challenge is to figure out if, by applying these operations starting from (sx, sy), we can eventually obtain the point (tx,
```

ty). If it's possible, return true; otherwise, return false.

To solve this problem, we can use the reverse thinking approach. Instead of starting from (sx, sy) and trying to reach (tx, ty)

ntuition

using the allowed operations, we start from (tx, ty) and try to work our way backwards to (sx, sy). This approach is valid because the operations are reversible. We repeatedly subtract the smaller of tx and ty from the larger until we either pass sx and sy or land exactly on them. During this

process, if tx is greater than ty, we know that tx had to be formed by adding ty to a smaller number in the previous step, so we perform tx %= ty. The same reasoning applies if ty is greater than tx.

While doing this, there are three cases: 1. If both tx and ty are greater than sx and sy respectively, we continue reducing tx and ty.

2. If tx becomes equal to sx, we check if ty can be reduced to sy by a multiple of tx. If so, it means we can reach (sx, sy) from (tx, ty).

exponentially.

3. The same check applies if ty becomes equal to sy.

If none of the conditions are met, then it's not possible to transform (sx, sy) to (tx, ty) using the operations, so we return

false. The time complexity of this approach is O(log(max(tx, ty))), which occurs due to the modulo operation that reduces tx and ty

sy, or until one of the coordinates matches sx or sy.

handle both cases to complete the algorithm:

true accordingly.

The implementation of the solution follows a reverse approach working backward from the target point (tx, ty) to the start point (sx, sy). Here's how the solution translates into code:

The solution starts by initializing a while loop that continues as long as both tx and ty are larger than sx and sy, but tx is not

equal to ty. This condition allows us to reduce tx and ty until either we can't reduce them anymore without going below sx or

- Inside the loop, we use the % (modulo) operator to reverse the operation as follows: • If tx > ty, then tx must have been formed by adding some multiple of ty to the previous x value, so we perform tx %= ty. This reverses the last operation that affected tx.
- If ty > tx, then we apply ty = tx for the same reason but in the vertical direction.

ensuring ty > sy and (ty - sy) % tx == 0. If this is the case, we return true.

1. We start from (tx, ty) which is (9, 4) and compare it with (sx, sy). Since tx > ty, we perform tx %= ty.

counterpart, it proves that the path from (sx, sy) to (tx, ty) cannot be achieved with the given operations.

If tx == sx and ty == sy at the same time, we've found the exact reverse path to (sx, sy), and the function returns true. If tx == sx, then ty must be reducible to sy by repeatedly subtracting tx (the same operation reversed). We check this by

After exiting the loop, either tx == sx and/or ty == sy, or both tx and ty have been reduced below sx and sy. We need to

- Similarly, if ty == sy, we check if tx > sx and (tx sx) % ty == 0 to determine if tx can be reduced to sx and return
- If none of the conditions are met, it means that we can't reach (sx, sy) from (tx, ty) by reversing the operations, so the function returns false.
- ty). Instead, by taking advantage of the mathematical properties of the operation, it quickly navigates to the solution or determines impossibility with a time complexity of O(log(max(tx, ty))).

This approach is efficient because it avoids the exponential time complexity of trying all possible paths from (sx, sy) to (tx,

Let's consider the problem with a small example: Imagine our starting point is (sx, sy) = (2, 4) and our target point is (tx, ty) = (9, 4). Can we transform the starting point to

the target point using the allowed operations? We apply the reverse approach:

4. We compare tx with sx. They are not equal, so we continue with the loop. 5. Since ty > tx, we perform ty %= tx.

2. After applying the modulo operation, tx is now 9 % 4 = 1.

3. Now, our target point (tx, ty) has changed to (1, 4).

From the example above, we note the following:

other can achieve the same via multiples.

subtraction operations (modulo operation).

Solution Implementation

6. After applying the modulo operation, ty is now 4 % 1 = 0. The target point is now (1, 0). 7. Comparing the new ty with sy, we see that ty < sy; we cannot reduce ty anymore without going below sy.

• After several steps, we've ended up with ty < sy, which violates the condition that it's only possible to either match the starting point exactly (in which case both tx and ty would match sx and sy) or reduce one of the target coordinates to match the starting point's while checking if the

If target_x is greater than target_y, reduce target_x

Check if the starting point is reached after breaking out of the loop

return target_y > start_y and (target_y - start_y) % target_x == 0

If only target_y matches start_y, check if we can reach the target point

• As a result, we would return false for this example. Key Takeaways:

• The reverse approach significantly simplifies the problem, turning an otherwise computationally expensive search into a series of simple

• Since we could not achieve a situation where tx or ty matches sx or sy respectively without the other target coordinate going below its starting

- If at any point during the reverse operation one of the target coordinates becomes less than its corresponding start coordinate, we can stop and return false because this means that the target point cannot be reached from the starting point.

if target_x > target_y:

target_y %= target_x

by repeatedly subtracting start_x from target_y

by repeatedly subtracting start_y from target_x

if (targetX == startX && targetY == startY) {

targetY %= targetX;

// If we have exactly reached the start point, return true.

if (targetX == startX && targetY == startY) return true;

// Thus, check if the difference is a multiple of startX.

// Thus, check if the difference is a multiple of startY.

If target_x is greater than target_y, reduce target_x

Check if the starting point is reached after breaking out of the loop

return targetY > startY && (targetY - startY) % startX == 0;

return true;

class Solution: def reachingPoints(self, start_x: int, start_y: int, target_x: int, target_y: int) -> bool: # Loop to transform the target point back towards the starting point while target_x > start_x and target_y > start_y and target_x != target_y:

Likewise, this modulo operation finds the steps from target_x to reach current target_y

The modulo operation finds how many steps can be taken from target_y to reach current target_x target_x %= target_y # If target_y is greater than target_x, reduce target_y else:

       # If neither target_x nor target_y matches, reaching the target point is not possible
       return False
Time and Space Complexity
```

Time Complexity The time complexity of the provided code primarily depends on the number of iterations it takes for either tx or ty to be reduced

if target_x > target_y:

return True

target_y %= target x

if target_x == start_x and target_y == start_y:

 $O(\log(\max(tx - sx, ty - sy))).$

Space Complexity

time. However, the number of iterations could be large if tx and ty are much larger than sx and sy. In the worst case, the modulo operation reduces the larger number by an amount proportional to the smaller number. Therefore, the time complexity is logarithmic in relation to the difference between the target and the start coordinates, or more formally,

to either sx or sy, or for tx to equal ty. In each iteration, either tx or ty is reduced by a modulo operation, which takes constant

The space complexity of the provided code is 0(1). This is because the algorithm only uses a fixed amount of additional space (for variables tx and ty), and there is no additional space usage that grows with the input size.
