1306. Jump Game III

**Depth-First Search Breadth-First Search Array** 

We enter a loop that continues until the queue is empty.

# **Problem Description**

You are given an array arr of non-negative integers and a starting index start. Your goal is to determine if you can jump to any index in the array where the value is 0. From each index i, you have two possible jumps: either i + arr[i] or i - arr[i]. However, you must stay within the bounds of the array; you cannot jump outside of it. The question is, can you find a path

through the array, jumping from index to index, that leads you to an index whose value is 0?

Intuition

## The intuition behind solving this problem lies in considering it as a graph traversal problem, where each index is a node, and a

Medium

(BFS) approach. BFS is especially useful here because it allows us to visit each node layer by layer, starting from the node we are given as start, and move onwards until we either find a node with the value 0 or exhaust all possible nodes that we can visit. To implement BFS, we can use a queue to keep track of the indices we need to explore. For each index, we check whether the value is 0; if it is, we've reached our goal, and the answer is True. If the value is not 0, we "mark" this index as visited by setting its value to -1 to avoid revisiting it, which would cause an infinite loop. We then add the new indices we can jump to the queue if

jump represents an edge between nodes. Since we want to explore all possible jumping paths, we can use a <u>Breadth-First Search</u>

we have not visited them yet and they are within the bounds of the array. We continue this process until our queue is empty or we find a value of 0. **Solution Approach** 

The solution utilizes the Breadth-First Search (BFS) algorithm to explore the array. The BFS algorithm is often used in graph

# Here's how the implementation of the BFS algorithm works in the context of this problem:

We initiate a queue (deque in Python) and add the starting index to it. This queue holds the indices that we need to visit.

Inside the loop, we pop an index i from the front of the queue, which is the current index we are visiting. We then check if the value at this index i is 0. If it is, it means we have successfully found a path to an index with value 0,

traversal to visit nodes level by level, and in this case, it helps to find the shortest path to an index with value 0.

- and we return True.
- If it's not 0, we consider it visited by marking arr[i] as -1. This prevents us from revisiting it because revisiting would mean we're going in circles and not exploring new possibilities.
- we check two conditions: The index must be within the bounds of the array (0 <= j < len(arr)).</li>

We look at the indices we can jump to from index i, which are i + arr[i] and i - arr[i]. For each of these two indices,

- The value at that index must not have been visited (indicated by arr[j] >= 0). If an index satisfies both conditions, we append it to the queue so we can visit it in a subsequent iteration. Once we have processed all possible jumps from the current index and added any new indices to visit to our queue, we
- continue to the next iteration of the loop. This process is repeated until either the queue is empty, which means we have visited all reachable indices and did not find a
- By following the above steps, we utilize the BFS algorithm to check every index we can reach and determine if there is any path leading to an index with a value of 0.
- Let's illustrate the solution approach with a simple example: Consider the input array arr = [4, 2, 3, 0, 3, 1, 2] and the starting index start = 5. Our target is to find out if by jumping

Following the BFS approach: We initialize a queue and add the starting index 5 to it. Our queue now looks like this: [5].

# We pop the first element from the queue, which is 5, and check the value of arr[5]. Since arr[5] = 1, it's not 0, so we

continue.

**Example Walkthrough** 

We check the jump positions from index 5: 5 - arr[5] and 5 + arr[5] (before arr[5] was marked as -1). These positions

value of 0 (hence we return False), or we find an index with value 0.

left or right, starting from arr[5], we can reach an index with the value 0.

Starting the loop, our queue is not empty.

are 5 - 1 = 4 and 5 + 1 = 6.

For the first jump position:

∘ Index 4 is within the bounds of the array and arr[4] = 3 (not visited yet), so we add index 4 to our queue. Our queue now looks like this: [4]. For the second jump position:

 $\circ$  Index 6 is also within the bounds and arr[6] = 2 (not visited), so we add index 6 to our queue. Our queue now: [4, 6].

We continue the loop, next popping index 4 from the queue. It's value is 3 (not 0), so we mark it as visited by setting arr[4] = -1. We examine the jump positions 4 + 3 = 7 (which is out of bounds) and 4 - 3 = 1.

 $\circ$  Index 1 is within bounds and arr[1] = 2 (not visited), so we add 1 to our queue. Queue: [6, 1].

conclude our search with a True. We have found a path to an index with value 0.

from collections import deque # Make sure to import deque from collections

# Pop the element from the aueue

current\_index = queue.popleft()

jump\_value = arr[current\_index]

queue.append(next\_index)

if arr[current index] == 0:

return True

We mark arr[5] as visited by setting it to -1. Now arr looks like this: [4, 2, 3, 0, 3, -1, 2].

positions 6 + 2 = 8 (out of bounds) and 6 - 2 = 4, but since arr[4] is already visited (marked as -1), we don't add it to the queue. Queue remains the same: [1].

The next index we pop from the queue is 6, and arr[6] was 2 before we mark it as visited (set to -1). We check the jump

Next, we pop index 1 from the queue. Here we find arr[1] = 2, and after marking it visited, we check positions 1 + 2 = 3

and 1 - 2 = -1 (out of bounds). Index 3 is within bounds and arr[3] = 0. We've found a value of 0, so we immediately

Thus, by using the BFS algorithm, we efficiently navigated through the possible jump indices to find a path from start to an

index where the value is 0.

# Check if the value at the current index is 0, if so we've reached the target and return True

# If valid and not visited, append this index to the queue for future processing

# Get the jump value from the array, which indicates how far we can jump from this index

for next index in (current index + jump value, current index - jump\_value):

# If we've processed all possible indices and haven't returned True, then return False

# Ensure the new index is within bounds and not already visited

if 0 <= next index < len(arr) and arr[next index] >= 0:

// Determines if we can reach any index with value 0 starting from 'start' index

# The time complexity of the given code would be O(N), where N is the size of the array. This is because in the worst-case

Time Complexity

scenario we might need to visit each element in the array once. The code performs a Breadth-First Search (BFS) by iterating over the array and only traversing to those indices that haven't been visited yet (marked with -1). Since we are checking each element to see if it is 0 (where the jump game ends), and the elements can only be added to the deque once (due to being marked as -1 after the first visit), the maximum number of operations is proportional to the number of

**Space Complexity** The space complexity of the code is also O(N) due to the deque data structure that is used to store indices that need to be visited. In the worst case, this could store a number of indices up to the size of the arr.

elements in arr.

The space complexity includes additional space for the deque and does not include the space taken up by the input itself. Since

we are reusing the input array to mark visited elements, no additional space is needed for tracking visited positions outside of the input array and the deque.
