Simulation

Problem Description

Tic-tac-toe is a classic game for two players, "A" and "B", played on a 3×3 grid. The objective is to be the first to get three of their own marks in a row either horizontally, vertically, or diagonally. In this LeetCode problem, we are given a list of moves where each move is represented by a pair of integers that correspond to a row and column on the grid. The task is to determine the outcome of the game based on the sequence of moves. The rules are as follows:

Players alternate turns, placing their mark on an empty cell.

Player "A" uses the mark 'X' and makes the first move, while player "B" uses the mark 'O'.

If all cells are filled without a winner, the game is a draw and "Draw" should be returned.

- The game ends when a player has three of their marks in a row or all cells are filled.
- If a player wins, their identity ("A" or "B") should be returned.
- If the game has not ended, "Pending" should be returned.

The array moves represents the game sequence where moves[i] = [row_i, col_i] is the i-th move played on the grid at the cell

defined by the row and column indices.

Intuition

The solution provided leverages a counting approach to keep track of the game's state without having to construct the entire grid after each move. Here's the intuition behind the solution:

 We create a count array cnt of length 8 to keep track of marks along the rows, columns, and diagonals. The first three positions are for the rows, the next three positions for the columns, and the last two for the two diagonals. We iterate over the moves inversely for both players, skipping moves alternatively (since players take turns).

- Each player's move is analyzed with respect to the potential winning conditions: filling a row, column, or diagonal. We increment the respective counter for the move made.
- After each move, we check if any counters have reached 3, indicating a winning condition.
- If there's a winner, we identify which player's turn it was based on whether the number of moves made so far is odd or even, and return "A" or "B" accordingly.
- If the game is not won and not all moves are played, we return "Pending" indicating unfinished status.
- This approach simplifies the problem by focusing only on the winning conditions without reconstructing the entire board for each
- **Solution Approach**

If no winner is detected and the total moves made are 9, we declare the game a draw.

Starting with the observation that a player wins if they achieve three of their symbols in a row, column, or diagonal, the code

implements an elegant solution to identify the game's status after each move is made.

1. Create a counter array cnt with 8 zeros, where cnt[0] to cnt[2] correspond to the three rows, cnt[3] to cnt[5] to the three

columns, and cnt[6] and cnt[7] to the two diagonals of the board. 2. Iterate over the moves in reverse order using the range range (n-1, -1, -2), where n is the length of the moves list. This

iteration goes backwards and skips every other move to alternate between players A and B as they play.

3. For each move, extract the row and column from moves [k]. Increment the respective counters in cnt for the row index i and column index j+3. This update simulates placing the 'X' or 'O' on the board.

indicative of a winning condition.

the code returns "Pending".

Example Walkthrough

Here is a step-by-step approach to the implementation:

move, which makes the solution more efficient.

- 4. Check for a diagonal match by:
- \circ Incrementing cnt [6] (the counter for the left-to-right diagonal) if i == j. Incrementing cnt [7] (the counter for the right-to-left diagonal) if i + j == 2. 5. After updating the cnt, check if any value in cnt has reached 3 using the condition any (v == 3 for v in cnt). This check is
- condition), the game ends in a Draw, and so we return "Draw". 8. In the final case where no winner is found and n is less than 9, not all cells have been filled, thus the game is still ongoing, and

7. If no winner is found and the total number of moves n is 9 (meaning every cell has been filled without achieving a winning

6. If there is a winner, return "B" if k is odd (since the moves list includes player A's moves first, odd indexes will belong to player B

during reverse iteration), or "A" if k is even, indicating it was player A's turn during the move that secured the win.

- This method is efficient because it works incrementally, only tracking the essentials for determining the game outcome and not reconstructing the entire board's state after each move. It effectively makes use of a single-pass and counter-based technique, which is ideal for this array-based simulation of the tic-tac-toe game.
- Let's consider an example game represented by the sequence of moves: 1 moves = [[0,0],[2,0],[1,1],[2,1],[2,2]]

In this example, player A (using 'X') makes the first move at the top-left corner of the grid (0,0), followed by player B (using 'O') making a move at the bottom-left corner (2,0). The game proceeds with each player taking turns. Now, let's walk through the moves according to the solution approach:

2. The length of the moves list is 5, and we start iterating from the last move to the first move, skipping every other one to simulate the alternating turns:

For k = 4, which is the move [2,2] by player A:

For k = 2, which is the move [1,1] by player A:

The row index is 2, so we increment cnt [2].

The row index is 1, so we increment cnt [1].

The column index is 1, so we increment cnt [4].

(Note: Player B does not contribute to diagonal counters in these moves.)

1. We initialize a counter array cnt with 8 zeros: cnt = [0,0,0,0,0,0,0,0].

- The column index is 2, so we increment cnt[5]. • Since the row and column indices are equal, indicating a diagonal, we increment cnt [6].
- 3. Then we iterate for player B:

For k = 3, which is the move [2,1] by player B:

- At this point, after the even-indexed moves by player A, cnt looks like this: [0,1,1,0,1,1,2,0].
 - The row index is 2, so we increment cnt [2]. The column index is 1, so we increment cnt [4].

4. After these iterations, we check if any counters reached the value of 3, which would indicate a win. Since none have, we

The indices are the same, indicating the diagonal again, so we increment cnt [6].

The current state of cnt is [0,1,2,0,2,1,2,0]. No values are 3, so no winner yet. 5. Since only 5 moves are made and the total number of moves is less than 9, we cannot have a 'Draw', so we return 'Pending'.

37 Time and Space Complexity

The time complexity of the given code is 0(1), as the function processes a fixed number (at most 9) of moves, regardless of the

input size. The logic within the loop has a constant number of operations (checking the status of the game board, incrementing

The space complexity of the code is also 0(1) because the amount of memory used does not depend on the input size either. The cnt list has a constant size of 8, and no additional memory is allocated that would depend on the input.
