The problem presents a Binary Search Tree (BST) and an integer k. The goal is to determine if there are any two distinct elements

Problem Description

within the BST that add up to k. The BST is a tree structure where the value of each node is greater than all the values in its left subtree and less than all the values in its right subtree. This special property will play a key role in solving the problem efficiently. The solution should return true if such a pair exists or false otherwise.

Intuition

The intuition behind the solution comes from the properties of a BST. In a sorted array, a common approach to find if two numbers sum up to k is to use two pointers, one starting from the beginning and one from the end, moving towards each other until they find a pair that adds up to k or until they meet. We can use a similar approach with a BST using an inorder traversal, which will give us the

elements in sorted order. However, instead of using two pointers, we can use a HashSet (vis in the provided code) to store the values we've seen so far as we traverse the tree. While traversing, for each node with value val, we check if k - val is in our HashSet. If it is, we've found a pair that adds up to k and we can return true. If not, we add val to the HashSet and keep traversing. This approach leverages the BST property to eliminate the necessity of having the sorted list beforehand, and the HashSet to check for the complement in 0(1)

1. Check if the complement of the current node's value (i.e., k - root.val) exists in the visited HashSet. 2. If the complement exists, return true as we found a valid pair. 3. If the complement does not exist, add the current node's value to the HashSet.

The provided solution uses Depth-First Search (DFS) to traverse the BST. The recursive dfs function checks if the current node is

4. Recursively apply the same logic to the left and right children of the current node, returning true if either call finds a valid pair.

- This solution effectively traverses the BST once, resulting in a time complexity of O(n) where n is the number of nodes in the BST,
- and a space complexity of O(n) for the storage in the HashSet.

both perform the search and to propagate the result of the search back up the call stack.

could potentially be a complement to a node we visit later in the traversal.

lookups, making our checks for the complement efficient.

average time complexity, leading to an efficient overall solution.

None and, if not, proceeds to do the following:

The solution implements a Depth-First Search (DFS) to traverse through the nodes of the Binary Search Tree. The DFS pattern is

chosen because it allows us to systematically visit and check every node in the BST for the conditions stipulated in the problem. Let's walk through the implementation step by step:

• A helper function named dfs is defined, which is recursively called on each node in the tree. The purpose of this function is to

• Inside the dfs function, we first check if the current node, referred to as root, is None. If it is, it means we have reached the end of a branch, and we return False because we cannot find a pair in a nonexistent (null) sub-tree.

Solution Approach

1 if root is None: return False • Next, we check if the difference between k and the value of the current node root val is in the set vis. If the difference is found,

- that means there is a value we have already visited in the tree that pairs with the current node's value to sum up to k. We then return True as we have found a valid pair.
- if k root.val in vis: return True

• If we haven't found a valid pair yet, we add the value of the current node to the vis set to keep a record of it. This is because it

• Finally, we need to continue the traversal on both the left and right subtrees. We recursively call the dfs function on root.left

and root right. We leverage the or operator to propagate a True result back up if either of the recursive calls finds a valid pair.

1 vis.add(root.val)

• The vis set is a crucial data structure utilized in this approach. Its main purpose is to keep track of all the values we have seen in

• The dfs function is then called from within the findTarget function, which initializes the vis set and starts the process. The

the BST during the traversal. The set is chosen because it provides an average-time complexity of 0(1) for both insertions and

search is kicked off at the root of the tree.

1 vis = set()

2 return dfs(root)

1 return dfs(root.left) or dfs(root.right)

complement values) to solve the problem in O(n) time complexity, where n is the number of nodes in the tree, while maintaining O(n) space complexity for the set. **Example Walkthrough**

By using the DFS traversal coupled with a set to record visited values, we efficiently search the BST for a pair of values that sum up

to k. This approach effectively uses properties of the data structure (BST), an algorithm (DFS), and a pattern (using a set to track

structure:

1. We start the DFS with the root of the BST, which is the node with value 5. We initialize an empty HashSet vis to keep track of

2. Since root is not None, we check if k - root.val (which is 9 - 5 = 4) is present in vis. It is not, so we proceed to add 5 to vis.

Let's consider a small example to illustrate the solution approach. Assume we have a Binary Search Tree (BST) with the following

the values we've encountered.

Python Solution

Definition for a binary tree node.

class TreeNode:

class Solution:

19

20

21

22

30

6. Since the node with value 2 has no children, we backtrack and apply DFS to the right child of 3, which is 4. Checking if k - 4 = 5is in vis and we find that it is, meaning we have discovered a valid pair (4 and 5) which adds up to k = 9.

been visited. By using a recursive DFS approach, we were able to keep the implementation clear and systematic.

Determines if there are two elements in the BST such that their sum is equal to a given target.

5. Next, we traverse to the left child of 3, which has the value 2. We check if k - 2 = 7 is in vis. It is not, we add 2 to vis.

Now, we will walk through the solution using the Depth-First Search (DFS) traversal and HashSet as described:

And let's say we want to find if there are any two numbers within this BST that add up to k = 9.

3. Now we apply DFS to the left child of 5, which has the value 3.

4. Again, we check if k - 3 = 6 is in vis. It is not, so we add 3 to vis.

def findTarget(self, root: Optional[TreeNode], k: int) -> bool:

:return: True if such a pair is found, False otherwise

Base case: if the node is None, return False

return depth_first_search(node.left) or depth_first_search(node.right)

:param root: Root node of the binary search tree

Helper function to perform a depth-first search

Time and Space Complexity

Here's the computational complexity breakdown:

The DFS traverses each node exactly once, irrespective of the tree structure, because we are looking at each value only once and checking if its complementary (k - root.val) is in the vis set.

Therefore, the time complexity is O(n), where n is the number of nodes in the binary tree.

Space complexity

Time complexity

The space complexity consists of two main components:

1. The space used by the vis set: In the worst case, it might store all the values contained in the tree, so it would be 0(n). 2. The space used by the call stack during the DFS: In the worst-case scenario of a completely unbalanced tree (where each node

The given Python code is aimed at determining whether there are two nodes in a binary tree that add up to a given sum k. To

achieve this, it performs a Depth-First Search (DFS) and uses a set vis to record the values it has encountered.

has only one child), the call stack would grow as large as the height of the tree, which would be O(n). Considering both components, the overall space complexity of the algorithm is O(n), with n being the number of nodes in the tree.
