1040. Moving Stones Until Consecutive II

Leetcode Link

Problem Description

The problem presents a game scenario with stones placed at various positions on the X-axis. You are given an array, stones, representing the positions of the stones. A stone becomes an endpoint stone if it is at either end of the sequence (smallest or largest position). The objective is to make moves to remove a stone from being an endpoint stone by placing it at a new unoccupied position.

game ends when you cannot make any more moves and the stones are in three consecutive positions. The problem asks for two outputs:

The rules of the game state that you cannot move an endpoint stone to a position where it continues to be an endpoint stone. The

The minimum number of moves required, represented by answer [0].

- Intuition

2. The maximum number of moves that can be made, represented by answer[1].

To figure out the solution, understand the following key points:

few moves as possible. This usually entails moving endpoint stones closer to the center. The edge case is when there's exactly one

make the sequence consecutive. Maximum Moves: For the maximum number of moves (mx), think of moving the endpoint stones away from the center to the farthest position possible inside the current stone range, but one at a time, to ensure they are not considered an endpoint stone anymore. It's a game of maximizing the number of moves by utilizing the current gaps to the fullest.

gap between two stones that's equal to the number of stones minus two - this would require two moves to fill in the positions and

Minimum Moves: To compute the minimum number of moves (m1), we aim to bring the stones into a consecutive sequence with as

The code's approach to solving for mi and mx involves sorting the stones array to process stone positions in a defined order. It then utilizes sliding window technique to find the minimum moves required to create a consecutive sequence. The maximum number of moves are computed considering the largest gaps on either end of the sorted array.

Solution Approach The solution follows these steps:

an ascending order which is crucial for the next steps.

whichever yields a larger value:

2. Initialize Variables: A variable n is used to store the number of stones, and mi is initialized with the value of n, to be later updated with the actual minimum moves.

3. Compute the Maximum Moves (mx): Calculate the maximum moves which can be made by considering one of two scenarios,

1. Sort the Array: The first step requires sorting the stones array. Sorting helps identify the endpoints easily and arrange stones in

- Moving the stone from the start to just after the second stone, i.e., stones[-1] stones[1] + 1 minus the number of stones excluding the moved stone.
- excluding the moved stone. The +1 in the formulas accounts for the fact that we want to include both endpoints in the range. These operations represent the case where you move the first or last stone to get the most number of moves without being an endpoint stone in the next move.

Moving the second last stone to just before the first stone, i.e., stones [-2] - stones [0] + 1 minus the number of stones

moves. Two pointers 1 (start of the window) and 1 (end of the window) iterate over the array to determine the smallest movement of stones necessary to reach a position where stones are in a consecutive sequence.

4. Sliding Window for Minimum Moves (mi): The next part of the code uses a sliding window approach to calculate the minimum

minus the size of the current window (n - (j - i + 1)). The code uses these techniques and conditional checks to ensure we find the least and the maximum number of moves to reach the

• The window size cannot be greater than n, so if the current window size exceeds n, the start of the window (1) is moved up.

∘ If the end of the window minus the start of the window plus one (j - i + 1) equals n - 1 and the range (x - stones [i]) is n

- 2, this means there is exactly one gap that requires two moves to fill. Otherwise, the minimum moves (mi) are updated to n

game's end goal. Finally, the function returns the list [mi, mx] containing the minimum and maximum moves possible.

understand how we get our answer with the minimum and maximum number of moves. 1. Sort the Array: The initial array is already sorted, which looks like [1, 3, 5, 7]. The endpoints here are 1 and 7.

2. Initialize Variables: The number of stones n is 4 in this case. We'll start with mi = 4 for the minimum moves. 3. Compute the Maximum Moves (mx):

Example Walkthrough

Moving the stone from the start (1) to just after the second stone (3) would be: 7 - 3 + 1 = 5 minus the number of stones

Moving the second last stone (5) to just before the first stone (1) would yield: 5 - 1 + 1 = 5 minus the remaining stones,

Assuming we have an array of stone positions given as stones = [1, 3, 5, 7]. Let's apply the solution approach to this array to

- 4. Sliding Window for Minimum Moves (mi): Using a sliding window, we check consecutive positions in the sorted array to calculate the fewest moves to get stones in a
 - We start with the window i = 0 and expand j till we reach 2, so we look at [1, 3, 5]. The window size here is 3, which is one less than n, and the range is 5 - 1 = 4, which is not n - 2. The stones in this window already form a consecutive

consecutive sequence.

again 3, resulting in 2.

So, in either case, the mx is 2.

min_moves = total_stones

sequence, so no moves needed.

excluding the moved one, which is 3, so 5 - 3 = 2.

we don't need any moves to achieve the consecutive sequence.

def numMovesStonesII(self, stones: List[int]) -> List[int]:

Initialize the minimum and maximum moves.

two moves are always required.

min_moves = min(min_moves, 2)

minMoves = Math.min(minMoves, 2);

// Return the minimum and maximum moves as an array

minMoves = Math.min(minMoves, numStones - (j - i + 1));

// within the current range.

return new int[]{minMoves, maxMoves};

} else {

stones.sort() # First, sort the stones in non-decreasing order.

stones[-2] - stones[0] - total_stones + 2)

Check for a special case where there's exactly one spot open

min moves = min(min_moves, total_stones - (j - i + 1))

within a group of consecutively placed stones - in this case,

if j - i + 1 == total_stones - 1 and current_stone - stones[i] == total_stones - 2:

Otherwise, the minimum moves are the total stones minus the size of the current window

total_stones = len(stones) # Find the total number of stones.

max_moves = max(stones[-1] - stones[1] - total_stones + 2,

and no moves are required. Since the stones within these windows are consecutive and we never encounter a situation with a gap of n = 2, mi is 0, as

Now let's consider the window [3, 5, 7] with i = 1 and j = 3. Similar to the first window, stones are already consecutive,

would return [0, 2]. Python Solution

Finally, we find that the minimum number of moves, mi, is 0 and the maximum number of moves, mx, is 2. Hence, answer = [mi, mx]

'i' will denote the start index of a window of stones 11 12 i = 0for j, current_stone in enumerate(stones): 13 # Slide the window towards the right if it's too long, 14

```

stones.sort((a, b) => a - b);

const numberOfStones = stones.length;

let minimumMoves = numberOfStones;

const maximumMoves = Math.max(

) - (numberOfStones - 2);

function numMovesStonesII(stones: number[]): number[] {

// Initialize minimum moves as number of stones

stones[numberOfStones - 1] - stones[1],

stones[numberOfStones - 2] - stones[0]

// Sort stones array so stones are in non-decreasing order

minimumMoves = Math.min(minimumMoves, 2);

// Return an array of minimum and maximum moves

// Calculate maximum moves by considering the farthest two stones

```
32
      return [minimumMoves, maximumMoves];
33 }
34
Time and Space Complexity
The time complexity of the given code is O(n \log n) and the space complexity is O(1).
Time Complexity
```

moved from the window once. Therefore, the loops combine for O(n) time.

1. stones.sort(): Sorting the stones requires $O(n \log n)$ time, where n is the number of stones.

// Check for the special case where there's one space for the last stone

2. The for and while loops: The outer for loop runs n times, and the inner while loop might seem to increase the complexity, but it does not. The while loop will execute at most n times in total across all iterations of the for loop because each stone is only

if (endIdx - startIdx + 1 === numberOfStones - 1 && stones[endIdx] - stones[startIdx] === numberOfStones - 2) {

// Otherwise, calculate the moves needed by the number of stones outside the current window

minimumMoves = Math.min(minimumMoves, numberOfStones - (endIdx - startIdx + 1));

Adding both complexities, the dominant term is the O(n log n) for the sort operation, leading to a total time complexity of O(n log

Space Complexity

1. The space complexity remains 0(1) since no additional space is used that scales with the input size. Only a fixed number of variables are used for tracking indices and the minimum and maximum moves, regardless of the number of stones.
