2498. Frog Jump II

Problem Description

You have an integer array stones where each element represents the position of a stone in a river, and the array is sorted in strictly increasing order. A frog starts on the first stone and wants to make it to the last stone before returning to the first stone. In doing so, the frog is allowed to jump to any stone, but only once per stone.

The length of a jump is calculated as the absolute difference between the positions of the current stone and the stone the frog jumps to. Thus, if the frog jumps from stones[i] to stones[j], the length of the jump is |stones[i] - stones[j] |.

and back. The goal is to determine the minimum cost of a path, meaning, to find out the smallest possible maximum jump length that the frog can achieve while still reaching the last stone and coming back to the first one.

A path's cost is determined by the longest (maximum length) jump the frog makes on its way from the first stone to the last stone

Intuition

maximum jump length. The fact that the area we cover is the river between the first and last stone, and we eventually need to return to the start, it is reasonable to consider that the costliest jumps will be at the beginning or end of the route. This is because the stones are sorted and there are no gaps, so the largest jumps will be between stones that are the farthest apart. We notice that the frog has two critical long jumps: the first jump into the river and the last jump out of the river. The first jump can

The intuition behind the solution lies in understanding how the cost of a path is defined and making strategic jumps that minimize the

only be between stones [0] and stones [1], and the last jump can be between any two consecutive stones since the frog must return to stones[0]. Hence, we arrive at the idea of checking every pair of stones that could represent the last jump (every two consecutive stones), and

then extract which of these calculated longest jumps represents the smallest maximum jump, yielding the minimum cost of a path. The implementation of the solution iterates through the stones array, starting from the second index (since the first jump is

predefined), and compares the length of the jump two stones apart, updating the answer to the maximum jump length seen so far.

for each such pair, calculate the longest jump that occurs if the frog were to make that particular pair its last jump sequence. We can

This effectively accounts for the costliest jump the frog makes if it decided to make that pair of stones the last jump of its return trip. By the end of the iteration, since all potential last jump pairs are accounted for, the ans variable holds the value of the minimum cost path. Solution Approach

comparison operation for each element to find the maximum jump length.

The core algorithm doesn't utilize advanced data structures or complex patterns but relies on understanding the problem and employing a simple iterative approach to solve it.

The solution uses a simple for-loop to iterate through the array of stones from the second stone onwards, and it performs a

1. Initialize ans with the difference between the first two stones, since the frog's first jump from stones [0] to stones [1] is

predetermined and represents the initial cost.

Here's a breakdown of the implementation steps with a focus on understanding the algorithm and patterns used:

at index i-1 and the one before it at index i-2. 3. Calculate the length of the jump from stones[i - 2] to stones[i] by taking the absolute difference: stones[i] - stones[i -

2. Iterate through the array of stones starting from index 2 (the third stone). For each stone at index i, consider the previous stone

2]. This represents the potential maximum jump length if stones [i - 1] and stones [i] are considered as the last jump on the

- way back. 4. Update the ans if the current jump length is greater than the previously recorded maximum jump length. This is done using the max function.
- 5. Repeat this process until all possible jump lengths (for when each pair of consecutive stones could be the frog's last jump back to the start) have been considered.
- 6. At the end of the loop, ans holds the minimum cost of the path that the frog can take. The reference solution doesn't apply complex algorithms or use additional data structures; it applies a direct approach that uses only

simple array indexing and built-in functions. This illustrates an important pattern in many coding challenges: sometimes the

Here's the essence of the code snippet that achieves this:

ans = stones[1] - stones[0] for i in range(2, len(stones)): ans = max(ans, stones[i] - stones[i - 2]) return ans

Note that the code above assumes that the input will always have more than two elements as per the constraints implied in the

straightforward solution is the most effective and efficient one.

```
problem description.
Example Walkthrough
```

1 def maxJump(self, stones: List[int]) -> int:

10], where each element signifies the stone's position in a river.

Let us consider a small example to illustrate the solution approach. Suppose we have the following integer array stones: [2, 4, 7,

 \circ ans = 2

 \circ ans = 4 - 2

 \circ ans = 5

Following the logic described above:

o ans = stones[1] - stones[0]

```
3. We make a jump from stones[0] to stones[2] (from position 2 to position 7):
```

1. Initialize ans with the difference between the first two stones.

```
Current jump length = stones[2] - stones[0]

 Current jump length = 7 - 2
```

Current jump length = stones[3] - stones[1]

6. Since 6 (current jump length) > 5 (ans), we update ans again.

Current jump length = 10 - 4

Current jump length = 6

The final ans = 6

Python Solution

13

14

stone, then the third stone and fourth stone.

Current jump length = 5 4. Since 5 (current jump length) > 2 (ans), we update ans.

2. Proceed through the stones to find the maximum jump required if the last jump back were between the second stone and third

5. Next, consider the stones at positions stones [1], stones [2], and stones [3] to simulate if the last jump is between stones [2] and stones[3].

```
\circ ans = 6
7. We have now considered all possible last jump pairs, and thus, the ans value is the minimum possible maximum jump length the
  frog can achieve when completing its path.
```

So, the minimum cost of a path which is the smallest maximum jump the frog has to make in this case is 6.

Current jump length would be between stones [1] and stones [3]: from position 4 to position 10.

from typing import List class Solution:

Iterate over the stones starting from the third stone.

max_jump = max(max_jump, stones[i] - stones[i - 2])

def maxJump(self, stones: List[int]) -> int:

Return the maximum jump distance found.

int maxJumpDistance = stones[1] - stones[0];

2 #include <algorithm> // Include the algorithm header for the 'max' function

// Import the algorithm's max function equivalent in TypeScript

// Function to determine the maximum jump between adjacent stones

max_jump = stones[1] - stones[0]

for i in range(2, len(stones)):

public int maxJump(int[] stones) {

15 return max_jump 16

Initialize the maximum jump distance as the distance between the first two stones.

Update the maximum jump distance if the current distance is larger.

For each stone, calculate the jump distance from the stone two positions before it.

// Loop through the array starting from the third stone for (int i = 2; i < stones.length; ++i) {</pre> // Calculate the jump distance between the current stone and the stone two steps back 10 int jumpDistance = stones[i] - stones[i - 2]; 11 12 // Update the maximum jump distance if the current jump is greater 13 maxJumpDistance = Math.max(maxJumpDistance, jumpDistance); 16 17 // Return the maximum jump distance found return maxJumpDistance; 18 19 20 } 21

// Initialize the maximum jump to the distance between the first two stones

// Method to calculate the maximum jump distance between consecutive stones

28 // let result = maxJump(stones);
   // console.log(result); // This would print the result of the maximum jump.
30
Time and Space Complexity
The given Python code snippet defines a method maxJump that determines the maximum jump between consecutive or alternate
```

stones in a list of stones represented by their positions in stones.

Time Complexity The time complexity of the code is O(n), where n is the length of the stones list. This is because there is a single for loop iterating

through the stones array, starting at the second index and performing a constant time operation (calculating the maximum jump and

updating ans) during each iteration.

Space Complexity

The space complexity of the code is 0(1), which means it is constant space complexity. Apart from the input list itself, the only additional storage used is a single variable ans to keep track of the current maximum jump, which does not rely on the size of the input.
