188. Best Time to Buy and Sell Stock IV Array **Dynamic Programming Leetcode Link** Hard

day i. Additionally, you're given an integer k. Your task is to calculate the maximum profit you can achieve from at most k

Problem Description You are given an integer array prices, which represents the price of a given stock on different days, where prices[i] is the price on

transactions. A transaction consists of buying and then selling one share of the stock — You can only hold one share of the stock at a time, meaning you need to sell it before buying another. To summarize, the goal is to find the best days to buy and sell the stock so that the total profit, after at most k transactions, is as high as possible without conducting simultaneous transactions.

Intuition

holding a stock.

Given the constraint of a maximum of k transactions, it's clear that this problem cannot be solved by a simple greedy strategy that tends to work when there's no limit on the number of transactions. Efficient solutions to this problem rely on dynamic programming, where we track the state of our transactions at each step.

• Every day, you have the option either to do nothing or to take an action (buy or sell), depending on whether you're currently

• If you're holding a stock, you can either sell it or continue holding it for potentially better future profits. • If you're not holding a stock, you can either buy a stock (provided you have remaining transactions) or wait.

The intuition behind the solution is the following:

Thus, a state is defined by three parameters: the current day, the number of transactions left, and whether you're holding a stock. The dynamic programming approach typically involves breaking down the problem into smaller subproblems and building up a

solution from there, using a table (or, in memory-efficient solutions, two arrays) to keep track of the state transitions—namely, the

maximum profit from each state. The transition rules govern how you can move from one state to another and thereby form the

essence of the solution. For any given day, the maximum profit depends on the maximum profits of the previous days and the current stock price. The

divided into overlapping subproblems that can be solved independently.

solution code simplifies the space complexity by maintaining only two columns for holding and not holding states, running through the prices, and updating the state values in place. This way, we derive our maximum profit without needing to store the entire table's

worth of data.

Solution Approach

The implementation for finding the maximum profit with at most k transactions uses dynamic programming. Dynamic programming is a method for solving complex problems by breaking them down into simpler subproblems. It is applicable when the problem can be

2. Base Case Initialization: o Initialize the first day's state because we know that on the first day (before any transactions and stock prices come into

Here's the approach:

1. State Definition:

 Define f with the dimensions [k + 1] by 2 to represent the state table where f[j][0] is the maximum profit up to day i with j transactions and not holding a stock, while f[j][1] is the maximum profit up to day i with j transactions and holding a stock.

play), if we are not holding a stock, our profit is 0, and if we are holding a stock, then the profit is negative because it's an

• For each day and for transaction counts from k down to 1 (to ensure we reset the holding state before using it for the next

• f[j][0] is updated to the maximum of either selling the stock we're holding at current price x or not selling it (keeping

• f[j][1] is updated to the maximum of either buying the stock at current price x using one of our transactions or not

Loop through each price x in prices[1:], starting from the second day, since the first day is used for initialization.

3 // Holding a stock

through k transactions.

Example Walkthrough

3. State Transition:

expense: -prices[0].

transaction) we update our states:

the previous profit without holding a stock).

 $[1] = \max(f[j-1][0] - \text{price}[i], f[j][1])$

to the maximum profit problem with at most k stock transactions.

buying it (keeping the previous profit with holding a stock). 4. State Transitions Equations: The transition function is based on the choices we have on each day i for transaction j: 1 // Not holding a stock 2 f[j][0] = max(f[j][1] + price[i], f[j][0])

This also adheres to the constraints that you must sell the stock before you can buy again.

5. Answer Retrieval: • The final answer is the profit at the last transaction having sold any stock, which is f[k][0].

The critical understanding in the dynamic programming approach involves deciding the state dimensions and transitions that capture

the essence of the problem while optimizing the space used by re-using the state information of the previous day as we move to the

next day. In terms of complexity:

• The time complexity of this algorithm is 0(n * k) because we go through all the stock prices (n steps) and for each price, we go

This presented approach succinctly captures the problem's constraints and optimizes for space while providing an efficient solution

Let's take an example to illustrate the solution approach for the problem statement given. Suppose we have the price array prices = [3,2,6,5,0,3] which represents the price of the stock on different days, and we're allowed at most k = 2 transactions.

oth transaction). Initially, our DP table looks like this (note that it has not yet been filled with meaningful values):

• The space complexity of this algorithm is O(k) since we only keep track of the most recent 2 * (k + 1) states.

1 f = [[0, -inf], // 0 transactions, not holding and holding (impossible) [0, -inf], // 1 transaction, not holding and holding [0, -inf], // 2 transactions, not holding and holding

We start by initializing our DP table f with dimensions [k + 1][2], meaning it would have size [3][2] for this example (including the

[0, -inf],

[0, -3],

[0, -inf]

Process Day by Day

Day 1: Price is 2.

[5, -2],

[0, -inf]

not). We keep -2.

Let's walk through the processing of each day:

Base Case

Initialization

our base case for holding a stock after 1 transaction is f[1][1] = -3. 1 f = [

Before any prices come into play, we cannot have a profit with 0 transactions, so f[0][0] is 0. On the first day, if we buy at price 3,

```
• f[1][1]: If we are not holding, we can buy at 2. So max(-3, -2) = -2 (we choose to buy at a lower price).
```

We update our states: 1 f = [[0, -inf],

• f[2][0]: Max of not doing a new transaction (0) or selling what we had from the previous transaction (6 - (-2) = 8). We choose

• f[2][1]: Max of buying a new one with the profit from the first transaction (5 - 6 = -1) or keeping the old case (-inf). We

(Note: As we do not have transaction 0 holding a stock (f[0][1]), it doesn't affect our calculations and stays -inf.)

• f[2][0]: Max of not doing a new transaction (8) or selling what we have (5 - (-1) = 6). We choose 8.

• f[1][0]: If we are holding, we can sell for a profit of 2 - (-3) = 5. So max(0, 5) = 5 (we choose to sell).

```
Day 2: Price is 6.
  • f[1][0]: Max of not selling (5) or selling what we have (6 - (-2) = 8). We choose 8 (we sell).
  • f[1][1]: Max of keeping the previous stock (-2) or buying new at 6 (but we would need 0 transactions left over, which we do
```

choose -1. [0, -inf],

```
Day 3: Price is 5.
  • f[1][0]: Max of not selling (8) or selling what we have (5 - (-2) = 7). We keep 8.
```

[0, -inf],

the same day).

holding a stock.

Java Solution

class Solution {

and f[2][0] would give us the answer.

return 0

f[transactions][holding]

for price in stock_prices[1:]:

[8, -2],

[8, -2],[8, -1]

8 (if we had sold earlier and bought today, this would be a second transaction).

Day 4: Price is 0. • f[1][0]: Max of not selling (8) or selling (0 - (-2) = 2), stick with 8. • f[1][1]: Max of keeping the old stock (-2) or buying a new one (8 - 0 = 8), but that's not valid (as we cannot sell and buy on

After processing all days, the DP table will reflect the maximum profit possible at each day for at most k transactions, not holding or

At the end of all the updates, the maximum profit with k transactions and not holding any stock on the last day will be given by f[k]

[0]. For our example with prices = [3,2,6,5,0,3] and k = 2, the final DP table would represent the maximum profit we can achieve,

• f[1][1]: Max of keeping the previous stock (-2) or buying new for less (-5 but using a previous transaction). We choose -2.

• f[2][1]: Max of keeping the old transaction (-1) or buying a new one (8 - 5 = 3), but that's a negative profit, so we stay with -1.

Python Solution from typing import List class Solution:

Edge case: if there are no prices or max transactions is zero

if not stock_prices or max_transactions == 0:

Initialize a 2D list to hold the state of profits

which is the negative value of the first price

for j in range(max_transactions, 0, -1):

for j in range(1, max_transactions + 1):

profits[j][1] = -stock_prices[0]

holding = 0 (not holding any stock), 1 (holding stock)

profits = [[0] * 2 for _ in range(max_transactions + 1)]

Loop through all prices starting from the second day

Go through all possible transaction numbers

Update the profit when not holding a stock:

Update the profit when holding a stock:

def maxProfit(self, max_transactions: int, stock_prices: List[int]) -> int:

Initialize the case where we've made one transaction, but are holding a stock,

max(selling the stock today, not selling and keeping the previous profit)

max(buying the stock today, not buying and keeping the previous profit)

// f[transactionCount][holding] with 0 meaning not holding a stock and 1 meaning holding a stock

// Max of (profit from the last transaction minus the price of today's stock, previous profit with holding a stock)

profits[transactionCount][1] = Math.max(profits[transactionCount - 1][0] - prices[dayIndex], profits[transactionCount]

// For the case where we have not made any transaction, but we are holding a stock,

// Return the maximum profit possible without holding a stock after k transactions

for (int transactionCount = 1; transactionCount <= k; ++transactionCount) {</pre>

// the initial profit should be negative, which is the cost of the stock on the first day

• f[2][0]: Max of not doing a transaction (8) or selling (0 - (-1) = 1), we keep 8.

Our updated DP table remains the same as the previous step:

• f[2][1]: Max of keeping the old stock (-1) or buying new (8 - 0 = 8), we keep -1.

Day 5 with price 3 is processed similarly, and we keep updating our DP table based on the rules.

32 # without holding any stock 33 return profits[max_transactions][0] 34

// Initialize an array to store the profit at each transaction stage

// Update profit for the case we buy the stock today:

Return the maximum profit after the allowable number of transactions

profits[j][0] = max(profits[j][1] + price, profits[j][0])

profits[j][1] = max(profits[j - 1][0] - price, profits[j][1])

16 // Iterate through each day starting from the second day for (int dayIndex = 1; dayIndex < numberOfDays; ++dayIndex) {</pre> 17 // Iterate for each possible transaction from k down to 1 18 for (int transactionCount = k; transactionCount > 0; --transactionCount) { // Update profit for the case we sell the stock today: 20 // Max of (previous profit for holding a stock and selling it today, previous profit without holding any stock) 21 22 profits[transactionCount][0] = Math.max(profits[transactionCount][1] + prices[dayIndex], profits[transactionCount][0]

return profits[k][0];

profits[transactionCount][1] = -prices[0];

public int maxProfit(int k, int[] prices) {

int[][] profits = new int[k + 1][2];

int numberOfDays = prices.length;

// The length of the given prices array

Time Complexity

complexity is O(k).

Typescript Solution

the prices list. The inner loop is running from k to 1, thus it runs k times for each iteration of the outer loop. Therefore, the total time complexity is the product of the two, which is O(N * k).

return profit[maxTransactions][0];

Time and Space Complexity

The given code has two nested loops:

- **Space Complexity**
- Before optimization, the solution uses a 2D list f with (k + 1) * 2 elements, regardless of the size of prices. Thus, the space
- According to the reference answer, by optimizing the first dimension of the space, the space complexity can be further reduced. This implies that instead of storing all k + 1 states for the 'sell' and 'buy' scenarios, we can only keep track of the current and

previous states. If we store just one state and update it as we go, we only need 2 * k space, one for each 'buy' and 'sell' at every transaction number up to k. Hence, after optimization, space complexity remains O(k) since it is not dependent on N and we are only optimizing in terms of k.

• The outer loop runs through the price list once, with the exception of the first element, so it runs in O(N), where N is the length of
