Linked List

Problem Description

The problem requires us to modify a linked list by removing all nodes that contain a specified value. Given the head of a linked list and an integer val, we must iterate through the linked list and delete any node where the Node, val is equal to val. The function should then return the head of the modified linked list, which might be different from the initial head if the head node itself needed to be removed.

### Intuition

To solve this problem, we need to iterate through the linked list and keep track of the previous node (pre) so we can modify its next pointer when we find a node that needs to be removed. The challenge is that the nodes to be removed can be anywhere in the list, including the head. To handle the case where the head itself needs to be removed, we introduce a dummy node with an arbitrary value that points to the head of the linked list. This dummy node acts as a placeholder that makes it easier to handle edge cases, particularly when we need to remove the head node.

Our approach involves iterating over the linked list with a pointer pre initialized to the dummy node. For each node, we check if the next node has a value equal to val. If it does not, we move pre to the next node. If it does, instead of moving to the next node, we change the next pointer of pre to skip over the node with the val we want to remove, effectively removing it from the linked list. We continue this process until we have checked all nodes. Finally, we return the next node of the dummy, which represents the new head of the modified linked list.

# Solution Approach

The implementation begins with creating a dummy node. This dummy node is a commonly used pattern when dealing with linked list modifications, as it simplifies edge case handling when the head of the list might be removed. We can say that the dummy node acts as a fake head (or a sentinel) to the list. The dummy node is linked to the actual head of the list.

After initializing the dummy node, we introduce a pointer pre that is used to traverse the list. This pointer starts at the dummy node.

The core of the solution is a while loop that continues until prenext is None (meaning we have reached the end of the list). Inside the

loop, the condition if pre.next.val != val is checked. If this condition is true, it means the current pre.next node does not need to be removed, and we can safely move pre to point to this node (pre = pre.next). If the condition is false, we have encountered a node with the value val, which must be removed. To remove this node, we alter pre.next to skip over the current pre.next node and point to pre.next.next. This effectively removes the unwanted node from the list. After the loop terminates, we return dummy next, which is the new head of the modified list. This works even if the original head was

removed because dummy next will now point to the first node with a value different from val. The aforementioned approach leverages basic linked list traversal and node skipping techniques. The dummy node pattern helps to

avoid special case handling for the head of the list. This pattern is also known for its utility in simplifying the code and making the algorithm cleaner and easy to understand. The overall time complexity of the solution is O(n), where n is the number of nodes in the list, since we may have to traverse the

entire list in the worst case. The space complexity is 0(1) as we only use a fixed amount of extra space. Example Walkthrough

## Let's assume we have a linked list $1 \rightarrow 2 \rightarrow 6 \rightarrow 3 \rightarrow 4 \rightarrow 5 \rightarrow 6$ and we want to remove all nodes with the value 6.

Here's a step-by-step illustration:

1. Create a dummy node with an arbitrary value (can be anything as it will not be used) and point its next to the head of the list. So,

now we have **dummy**  $\rightarrow$  1  $\rightarrow$  2  $\rightarrow$  6  $\rightarrow$  3  $\rightarrow$  4  $\rightarrow$  5  $\rightarrow$  6. 2. Initialize a pointer pre to point at the dummy node. So, pre is now pointing to dummy.

3. Begin iterating over the list. Since presnext (the first 1 node) does not have the value 6, we move pre to point to the 1 node.

- 4. Continue to the next node with value 2. The value 2 is not 6 either, so we move pre to this node. 5. The next node has the value 6, which is the value we want to remove. We change pre.next to skip this 6 node and point to its
- next node, which is 3. So now pre (which points to 2) has its next pointing to 3. The list now effectively looks like this: dummy →  $1 \rightarrow 2 \rightarrow 3 \rightarrow 4 \rightarrow 5 \rightarrow 6$ . 6. Move to the next nodes with values 3, 4, and 5 in the same manner since their values are not 6.
- 7. The next node with value 6 is again the node we want to remove. We change pre.next to skip this node and point to the next, which is null. The modified list now looks like this: dummy  $\rightarrow 1 \rightarrow 2 \rightarrow 3 \rightarrow 4 \rightarrow 5 \rightarrow \text{null}$ .
- 8. Since we've reached the end of the list (pre.next is null), we stop iterating.
- 4 -> 5, as all 6 nodes have been removed.

def removeElements(self, head: ListNode, val: int) -> ListNode:

Therefore, by using a dummy node and the pointer pre, we managed to remove all the nodes with the value 6 without having to deal with special cases like the head of the list being removed. This demonstrates the elegance and effectiveness of the solution

9. Finally, we return the node right after our dummy, which is the new head of the modified list. The returned list is 1 -> 2 -> 3 ->

**Python Solution** 

#### def \_\_init\_\_(self, val=0, next=None): self.val = val self.next = next

class Solution:

class ListNode:

approach.

```
# Create a dummy node that acts as the new head of the list with a sentinel value
           dummy_node = ListNode(-1)
           dummy_node.next = head
11
12
           # Initialize a pointer to track the current node we're examining
13
           current_node = dummy_node
14
15
           # Iterate over the list
16
           while current_node.next is not None:
               # If the value of the next node is the one we want to remove
               if current node.next.val == val:
19
                   # Remove it by skipping the node
20
                   current_node.next = current_node.next.next
22
               else:
23
                   # Move to the next node otherwise
24
                   current_node = current_node.next
25
26
           # Return the modified list, starting from the node after the dummy node
27
           return dummy_node.next

       // This points to the current node we're examining, starting from the dummy.
10
       let current: ListNode = dummy;
11
12
13
       // Iterate through the list as long as the next node exists.
       while (current.next !== null) {
14
15
           // If the value of the next node is the target value, bypass the next node.
           if (current.next.val === val) {
16
               current.next = current.next.next; // Skip the node to remove it.
17
           } else {
               current = current.next; // Move to the next node if it's not to be removed.
20
```

#### 22 // Return the next node of the dummy, which represents the new head after removals. 23 24 return dummy.next; 25 }

26

Time and Space Complexity **Time Complexity** 

The time complexity of the provided code is O(n), where n is the number of elements in the linked list. The while loop iterates

### through each node in the linked list a single time, checking if the node's value matches the target value val and removing it if necessary.

that would scale with the size of the input.

Space Complexity The space complexity of the provided code is 0(1). This is because the code only uses a constant amount of extra space: one dummy node (dummy) and one pointer (pre). The removal of elements is done in-place, not requiring any additional data structures
