517. Super Washing Machines

Array

Problem Description

Greedy

Hard

aligned in a row, and you can make a move where you choose any m machines (where 1 <= m <= n) and pass one dress from each chosen machine to one of its adjacent machines simultaneously. Your goal is to find the minimum number of moves required to redistribute the dresses so that all the machines have the same

In this problem, you are given n super washing machines, each initially containing a certain number of dresses. The machines are

number of dresses. If it's not possible to reach this balance, the function should return -1. To summarize:

• You have an array machines representing the number of dresses in each washing machine. You need to make all the washing machines have an equal number of dresses using the fewest moves possible.

- A move consists of choosing a subgroup of machines and shifting a dress from each one to an adjacent machine.
- You must determine the minimum moves required, or return -1 if equal distribution isn't possible.

impossible to equally distribute the dresses since you can't split a dress. This is the first check made: if the total number of dresses is not divisible by the number of machines, the method will immediately return -1.

Assuming equal distribution is possible, our goal is to identify how far each machine is from the average and to calculate the number of steps needed to equalize the distribution. The solution does this by:

To solve this problem, one must understand that if there is an average number of dresses per machine that isn't a whole number, it's

 Calculating the average number of dresses per machine (k). Initializing two variables: s, which will maintain the cumulative difference from the average at each step, and ans, which will hold

With each iteration over the machines, we:

- Subtract the average k from the current number of dresses to find how many dresses need to be passed onto or received from adjacent machines (x -= k).

• Update ans with the maximum of its current value, the absolute current imbalance abs(s), and the current machine's specific imbalance x.

the maximum number of moves observed so far.

Here's a step-by-step breakdown of the solution approach:

average by subtracting the average k from x (x -= k).

The previous maximum number of moves ans

balance the dresses across all washing machines.

redistributions might be happening simultaneously during each move.

individual and cumulative imbalance).

Example Walkthrough

- The absolute current imbalance abs(s) represents a sequence of redistributions among machines up to the current point. Finally, ans is the accumulated aggregate of moves required, which gets returned as the minimum number of moves to make all
- washing machines have the same number of dresses.

Add this difference to the cumulative sum s, which shows the total imbalance after the current machine.

The solution uses a greedy algorithm to redistribute the dresses across the washing machines. The main principle behind the

algorithm is that, at each step, the algorithm looks for the best local move that reduces the imbalance without caring for a global plan. To implement this, we use a single pass through the machines array, accumulating the necessary information to determine the

necessary for an equal distribution. If not, we know immediately that the problem has no solution (return -1).

machines, and ans is also set to 0 and will keep a record of the maximum number of moves needed at any point.

1. Calculate Total and Average: Determine the total number of dresses (sum(machines)) and the average (k), which is the target number for each machine to reach. Simultaneously, check if the total sum is divisible by the number of machines (n), which is

minimum number of moves.

Solution Approach

3. Iterate Through Machines: Iterate through each washing machine using x to represent the number of dresses in the current machine.

4. Calculate the Local Imbalance: For each machine, calculate how many dresses it needs to give away or receive to reach the

5. Update the Cumulative Imbalance: Accumulate the current machine's imbalance to s (s += x). This gives us a cumulative sum

2. Initialization: Initialize two variables: s is set to 0 and will be used to track the running imbalance as we iterate through the

- at each point which represents the net dresses that need to be moved after considering the redistribution up to that machine. 6. Determine Maximum Moves: After each adjustment, update ans to be the maximum of:
- and all previous machines to achieve balance. • The current machine's specific surplus or deficit x, which shows the minimum moves the current machine alone needs irrespective of the cumulative sum.

The algorithm uses a very straightforward data structure - a simple array to represent the machines and their respective counts of

This approach effectively balances the load across all machines in the minimum number of moves, taking into account that multiple

7. Return: After processing all machines, you're left with the maximum value in ans that represents the minimum moves required to

• The absolute value of the current cumulative imbalance abs(s), which indicates the minimum moves required for the current

dresses. The pattern employed here is largely one of accumulation and tracking the maximum requirement, which is typical of problems where you must consider a running total and update an answer based on local constraints (in this case, the machine's

Let's assume we have an array of washing machines where [1, 0, 5] represents the number of dresses in the respective machines. Let's walk through the solution approach step-by-step. 1. Calculate Total and Average:

• The total number of dresses is evenly divisible by the number of machines, so a solution is possible. 2. Initialization:

4. Calculate the Local Imbalance and Update the Cumulative Imbalance: \circ For the first machine, x = 1. We need x to be equal to the average k = 2. Thus, x -= k gives us -1. The machine needs 1

dress.

7. Return:

if remainder:

max moves = 0

return max_moves

balance = 0

return -1

Iterate over each machine.

for dresses_in_machine in machines:

public int findMinMoves(int[] machines) {

for (int dresses : machines) {

return -1;

totalDresses += dresses;

// Calculate the total number of dresses

if (totalDresses % machines.length != 0) {

if (totalDresses % numMachines != 0) {

for (int dressesInMachine : machines) {

// Update the cumulative imbalance

cumulativeImbalance += imbalance;

// 1. The current maxMoves,

int averageDresses = totalDresses / numMachines;

// Calculate the imbalance for the current machine

int imbalance = dressesInMachine - averageDresses;

// Calculate the average number of dresses per machine for balanced state

// Initialize cumulative imbalance and the answer (max number of moves required)

// The minimum number of moves required is the maximum of three values:

maxMoves = max({maxMoves, abs(cumulativeImbalance), imbalance});

// Return the minimum number of moves required to balance all machines.

// 3. The current imbalance (if a machine requires more moves on its own).

// 2. The absolute value of cumulative imbalance (for adjustments across machines),

return -1;

int maxMoves = 0;

return maxMoves;

int cumulativeImbalance = 0;

// Iterate over each machine

 \circ Determine maximum moves and update ans. Ans will be the max of ans, abs(s), and abs(x), so ans = max(0, 1, 1) = 1.

 \circ Update s with x. Now, s += (-2) => s = -3.

 \circ Update ans. ans = max(3, abs(0), abs(3)) = 3.

 \circ The total sum of dresses is 1 + 0 + 5 = 6.

• The number of machines, n, is 3.

 \circ We set s = 0 and ans = 0.

3. Iterate Through Machines:

• Update ans. ans = max(1, abs(-3), abs(-2)) = 3. 6. Iterate to the Third Machine:

 \circ Update s with x. Now, s += 3 => s = 0. All machines are now balanced.

 \circ Calculate the average dresses per machine, k, which is sum / n = 6 / 3 = 2.

We will iterate through each machine, starting from the first.

 The algorithm returns 3 as the minimum number of moves required to balance the dresses across all washing machines. In summary, the example demonstrates how the algorithm checks for the possibility of equal distribution, iterates to calculate

individual and cumulative imbalances and continuously updates the number of moves required based on the maximum imbalance

observed at each step. The final answer of 3 moves accounts for the most demanding redistribution that occurs during the process.

23 balance += dresses_to_move 24 # The maximum number of moves required is the maximum of three values: 26 # 1. Current max_moves (the max encountered so far) 27 # 2. The absolute balance (as we may need to move dresses across multiple machines) 28 # 3. Dresses to move for the current machine (as it may require a lot of adding/removing)

 \circ Update s with x. Now, s = -1.

5. Iterate to the Next Machine:

The iteration is complete and the maximum value in ans is 3.

 \circ For the second machine, $x = \emptyset$. To reach the average k, it needs 2 dresses. Thus, x = k gives us -2.

 \circ For the third machine, x = 5. To reach the average k, it must give away 3 dresses. Thus, x = k gives us 3.

class Solution: def findMinMoves(self, machines: List[int]) -> int: # Calculate the length of the machines list. machine_count = len(machines)

Calculate the number of dresses to move for this machine to reach the expected count.

// If total number of dresses is not divisible by the number of machines, there is no solution

Increment the balance, which represents the ongoing "debt" or "surplus" from left to right.

Compute total dresses and the expected dresses per machine, along with a remainder.

If there is a remainder, we can't equally distribute dresses to all machines.

total_dresses, remainder = divmod(sum(machines), machine_count)

Initialize variables for the answer and the running balance.

dresses_to_move = dresses_in_machine - total_dresses

max_moves = max(max_moves, abs(balance), dresses_to_move)

int totalDresses = 0; // Sum of all dresses across the machines

Return the maximum number of moves needed to balance all machines.

27
       return minMoves;
28 }
29
Time and Space Complexity
The provided code examines an array of machines representing the number of dresses in each laundry machine and calculates the
minimum number of moves required to equalize the number of dresses in all machines. Here's the computational complexity analysis:
```

 Time Complexity: The function findMinMoves involves a single for loop that iterates over the list of machines exactly once. Within this loop, only constant-time operations are performed: subtraction, addition, comparison, and assignment. Therefore, the time complexity is

The final time complexity is O(n).

few integer variables are used (n, k, mod, ans, and s). There are no data structures that grow with the size of the input. Therefore, the space complexity is 0(1) for the constant extra space used.

 Space Complexity: The space complexity is calculated based on the additional space used by the algorithm aside from the input itself. Here, only a

directly proportional to the length of the machines list, which is n.
